Another Derivative of Albumen with Concentrated Sulphuric Acid.—It is well known that albumen swells up considerably in concentrated sulphuric acid, but no investigation has been made as to what this product really is. I mixed in a mortar 1 part of albumen gradually with 10-15 parts of concentrated sulphuric acid, and allowed it to stand in the cold for one day; the mass was then treated with cold water till the free SO₄H₂ was all removed; the flocculent mass was placed in a dilute potassa solution (1 to 6—8), stirred sometimes, allowed to stand in the cold for one day, filtered, precipitated by acetic acid, the precipitate washed and dried. Analysis showed that it is albumen-sulphonic acid. It contains twice as much sulphur as the albumen itself, is insoluble in water, alcohol, and dilute acids, but soluble in alkalies, wherein it swells up considerably before the real solution slowly takes place. On boiling these solutions, decomposition takes place. I shall make further investigations on this subject.

ON THE ELECTROMOTIVE POWER OF METALLIC SULPHIDES.*

By WILLIAM SKEY,
Analyst to Geological Survey of New Zealand.

In this paper the author shows by a series of experiments that several of those sulphides which are conductors of electricity have the capacity of generating strong electric currents in those solutions frequently having contact with them in a natural way.

These currents when generated from a single pair, even of dissimilar sulphides, have an intensity so great that when allowed to pass into certain metallic solutions these solutions are decomposed, the metal being deposited in a coherent form.

This was demonstrated before the Society in the following manner:—

A mass of iron pyrites and another of galena were partially immersed in a vessel charged with sea water. To each of these minerals copper wires were attached at a distance of about 3 inches from the water-line, the intervening surface of the minerals being kept dry. That wire connected with the iron pyrites was placed in a solution of sulphate of copper contained in a separate vessel—the other wire was fastened to a thin piece of platinum foil—which foil was also set in the metallic solution facing the copper wire.

In a short time, the platinum foil was shown to be electrotyped with a regular film of copper wherever it had contact with the liquid, clearly showing that voltaic action had been developed by these sulphides, the galena forming the positive element of the pair.

A series of such pairs the author thought would properly be named a sulphide battery in accordance with the custom hitherto obtaining by which new forms of batteries are designated after some distinguishing or novel feature in them.

Gold was found to be reduced from its chloride by several of the metallic sulphides; both the electrodes in these cases were of platinum. Certain silver and platinum solutions were also effected in this manner.

Other sulphides manifest the same phenomena when paired among themselves.

The annexed column represents those which have been tested to this date, the arrangement of which is from positive to negative; the exciting solution is sea water.

Any two of these connected as described will be found positive and negative respectively; that occupying relatively the highest position in the column being always the positive one.

- Protosulphide of iron.
- Protosulphide of manganese (manganese blende).
- Protosulphide of zinc (as zinc blende).
- Bisulphide of tin.
- Protosulphide of mercury.
- Protosulphide of silver, chemically prepared.
- Protosulphide of lead (as galena).
- Subsulphide of copper (as copper glance).
- Ferrosulphide of copper (as copper pyrites).
- Bisulphide of iron (as cubical pyrites).
- Sulphide of antimony (as stibnite).
- Sulphide of gold.
- Sulphide of platinum.
- Sulpho-arsenide of iron (as mispickel).
- Carbon (graphite) sulphurised.

In connection with this table it was found that in the same solution zinc was positive to protosulphide of iron, while silver places itself between the sulphides of silver and lead; platinum between sulphide of platinum and mispickel; and, finally, carbon places itself below sulphurised carbon, to which it is, therefore, negative.

* Abstract of a Paper read before the Wellington Philosophical Society, January 29th, 1871.

The author on commenting upon what this table discloses, alludes to the singular circumstance that galena should prove to be more easily affected by such saline solutions than copper pyrites, as under ordinary circumstances it appears unalterable, copper pyrites, on the other hand, very soon discolouring.

As to the intensity of the electric current which some of these sulphides are capable of generating, the author thinks it little, if anything, inferior to that produced by zinc in similar solutions, and while its development is slower, he assumes the absolute quantity generated by the complete oxidation of iron pyrites would be about four times that yielded by the oxidation of this metal.

These results lead the author to believe that much of our native silver and gold has been electro-deposited from saline solutions by voltaic action set up by the contact of dissimilar sulphides, or of sulphides with more negative substances, such as hæmatite, magnetite, or ferruginous rocks.

They further lead him to think that those traces of electric currents discovered about forty years ago by Mr. Fox to occur in mineral lodes generally are produced by the oxidation of these sulphides, and so do not appear to be either the results of magnetic induction or of changes or differences in the temperature of adjoining rock masses, to either of which these currents have hitherto been generally attributed.

The author concludes his paper by offering the suggestion that "possibly a table like the one here constructed, when amended and enlarged by the results of further and more extensive researches upon pure, mixed, and native sulphides in this direction, may be useful to chemical geology in its attempts to trace back the history of our metalliferous deposits, since it shows (by the use of a thoroughly reliable and simple process) the relative tendency of various sulphides to decompose in those kinds of solutions most likely to have contact with them in the situations where they naturally occur."

ON THE REVIVED THEORY OF PHLOGISTON.*

By WILLIAM ODLING, M.B., F.R.S.

Fullerian Professor of Chemistry, Royal Institution.

(Concluded from page 245.)

VERY different is the view of phlogiston to be gathered from the writings of Dr. Watson, for example, who was appointed Professor of Chemistry at Cambridge in 1764, became Regius Professor of Divinity in 1771, and Bishop of Llandaff in 1782. This cultivated divine, indifferent, it is true, to the novel questions by which in less placid regions men's minds were so deeply stirred, amused the leisure of his dignified University life by writing scholarly accounts of the chemistry he had formerly been his province to teach; and in the first volume of his well-known "Chemical Essays," published in 1781, the following excellent account of phlogiston is to be found:—

"Notwithstanding all that perhaps can be said upon this subject, I am sensible the reader will still be ready to ask, *What is phlogiston?* You do not surely expect that chemistry should be able to present you with a handful of phlogiston, separated from an inflammable body; you may just as reasonably demand a handful of magnetism, gravity, or electricity to be extracted from a magnetic, weighty, or electric body. There are powers in nature which cannot otherwise become the objects of sense, than by the effects they produce; and of this kind is phlogiston. But the following experiments will tend to render this perplexed subject somewhat more clear.

"If you take a piece of *sulphur* and set it on fire, it will burn entirely away, without leaving any ashes or yielding

any soot. During the burning of the sulphur, a copious vapour, powerfully affecting the organs of sight and smell, is dispersed. Means have been invented for collecting this vapour, and it is found to be a very strong acid. The acid thus procured from the burning of sulphur, is incapable of being either burned by itself, or of contributing towards the support of fire in other bodies; the sulphur from which it was procured was capable of both: there is a remarkable difference, then, between the acid procured from the sulphur and the sulphur itself. The acid cannot be the only constituent part of sulphur; it is evident that *something* else must have entered into its composition, by which it was rendered capable of combustion. This something is, from its most remarkable property, that of rendering a body combustible, properly enough denominated the food of fire, the *inflammable principle*, the *phlogiston*. . . . This inflammable principle, or phlogiston, is not one thing in animals, another in vegetables, another in minerals; it is absolutely the same in them all. . . . This identity of phlogiston may be proved from a variety of decisive experiments; I will select a few, which may at the same time confirm what has been advanced concerning the constituent parts of sulphur.

"From the analysis or decomposition of sulphur effected by burning, we have concluded that the constituent parts of sulphur are two—an *acid* which may be collected, and an *inflammable principle* which is dispersed. If the reader has yet acquired any real taste for chemical truths, he will wish to see this analysis confirmed by synthesis; that is, in common language, he will wish to see sulphur actually made by combining its acid with an inflammable principle. It seldom happens that chemists can reproduce the original bodies, though they combine together all the principles into which they have analysed them. . . . In the instance, however, before us, the reproduction of the original substance will be found complete.

"As the inflammable principle cannot be obtained in a palpable form separate from all other bodies, the only method by which we can attempt to unite it with the acid of sulphur must be by presenting to that acid some substance in which it is contained. Charcoal is such a substance; and by distilling powdered charcoal and the acid of sulphur together, we can produce a true yellow sulphur, in no wise to be distinguished from common sulphur. This sulphur is formed from the union of the acid with the phlogiston of the charcoal; and the charcoal may by this means be so entirely robbed of its phlogiston, that it will be reduced to ashes, as if it had been burned.

"I will in this place, by way of further illustration of the term phlogiston, add a word or two concerning the necessity of its union with a metallic earth, in order to constitute a metal. Lead, it has been observed, when melted in a strong fire, burns away like rotten wood; all its properties as a metal are destroyed, and it is reduced to ashes. If you expose the ashes of lead to a strong fire, they will melt; but the melted substance will not be a *metal*, it will be a yellow or orange-coloured *glass*. If you pound the glass, and mix it with charcoal dust, or if you mix the ashes of the lead with charcoal dust, and expose either mixture to a melting heat, you will obtain, not a *glass*, but a metal, in weight, colour, consistency, and every other property the same as lead. The ashes of lead melted *without* charcoal become *glass*; the ashes of lead melted *with* charcoal become a *metal*. The charcoal, then, must have communicated *something* to the ashes of lead, by which they are changed from a glass to a metal. Charcoal consists of but two things—of ashes and of phlogiston; the ashes of charcoal, though united with the ashes of lead, would only produce glass; it must, therefore, be the other constituent part of charcoal, or phlogiston, which is communicated to the ashes of lead, and by an union with which the ashes are restored to their metallic form. The ashes of lead can never be restored to their metallic form without their being united with

* A Lecture delivered at the Royal Institution of Great Britain, April 28th, 1871.

some matter containing phlogiston, and they may be reduced to their metallic form by being united with any substance containing phlogiston in a proper state, whether that substance be derived from the animal, vegetable, or mineral kingdom; and thence we conclude not only that phlogiston is a necessary part of a metal, but that phlogiston has an identity belonging to it, from whatever substance in nature it be extracted. And this assertion still becomes more general, if we may believe that metallic ashes have been reduced to their metallic form, both by the solar rays and the electrical fire."

The foregoing account by Dr. Watson is almost a translation from Stahl's "*Zymotechnica Fundamentalis, simulque experimentum novum sulphur verum arte producendi*," in which he establishes what may be called the permanency of chemical substance—that metallic lead is reproducible from the ashes of lead, *sulphur verum* from the acid of sulphur. And, whether or not taking note of the oxidations and deoxidations effected, how little differently, even at the present day, would the actions referred to be described and explained. Is it not our habit to say that charcoal and sulphur and lead are bodies possessing potential chemical energy—that is, phlogiston; that in the act of burning, their energy which was potential becomes kinetic or dynamical, and is dissipated in the form of light and heat; that the products of their burning (including the gaseous product now known to be furnished by the burning of charcoal) are substances devoid of chemical energy, that is of phlogiston; that when the acid substance furnished by burning sulphur is heated with charcoal, some energy of the unburnt charcoal is transferred to the burnt sulphur, just as some energy of a raised weight may be transferred to a fallen one, whereby the burnt sulphur is unburnt, provided with energy, and enabled to burn again, and the fallen weight is lifted up, provided with energy, and enabled to fall again; that the potential chemical energy of metallic lead did not originate in the lead, but is energy or phlogiston transferred thereto from the charcoal by which it was smelted; and lastly, that the chemical energy of the charcoal itself, its capability of burning, its power of doing work, in one word its phlogiston, is merely a portion of energy appropriated directly from the solar rays.

If this be a correct interpretation of the phlogistic doctrine, it is evident that the Stahlans, though ignorant of much that has since become known, were nevertheless cognisant of much that became afterwards forgotten. For most of what has since become known, mankind are indebted to the surpassing genius of Lavoisier; but the truth which he established, alike with that which he subverted, is now recognisable as a partial truth only; and the merit of his generalisation is now perceived to consist in its addition to—its demerit to consist in its supersession of—the not less grand generalisation established by his scarcely remembered predecessors. This being so, the relationship to one another of the Stahlian and Lavoisierian theories of combustion furnishes an apt illustration of the general truth set forth by a great modern writer, that "in the human mind, one-sidedness has always been the rule, and many-sidedness the exception. Hence, even in revolutions of opinion, one part of the truth usually sets while another rises. Even progress, which ought to superadd, for the most part only substitutes one partial and incomplete truth for another; improvement consisting chiefly in this, that the new fragment of truth is more wanted, more adapted to the needs of the time, than that which it displaces."

The partial truth contributed by Lavoisier was indeed more wanted, more adapted to the needs of the time, than the partial truth which it displaced. To him chemists are indebted for their present conception of material elements; and especially for their knowledge of the part played by the air in the phenomena of combustion, whereby oxygenated compounds are produced. The phlogistians, indeed, were not unaware of the necessity of air to combustion, but being ignorant of the nature of air were

necessarily ignorant of the function which it fulfilled. To burn and to throw off phlogiston being with them synonymous expressions, the air was conceived to act by somehow or other enabling the combustible to throw its phlogiston off; and a current of air was conceived to promote combustion by enabling the combustible to throw its phlogiston off more easily. Moreover, contact of air was not essential to combustion, provided there was present instead some substance, such as nitre, which equally with, or even more effectively than air, could enable the combustible to discharge itself of phlogiston. But while the phlogistians, on the one hand, were unaware that the burnt product differed from the original combustible otherwise than as ice differs from water, by loss of energy, Lavoisier, on the other hand, disregarded the notion of energy, and showed that the burnt product included not only the stuff of the combustible, but also the stuff of the oxygen it had absorbed in the burning. But, as well observed by Dr. Crum-Brown, we now know "that no compound contains the substances from which it was produced, but that it contains them *minus* something. We now know what this something is, and can give it the more appropriate name of potential energy; but there can be no doubt that this is what the chemists of the seventeenth century meant when they spoke of phlogiston."

Accordingly, the phlogistic and antiphlogistic views are in reality complementary and not, as suggested by their names and usually maintained, antagonistic to one another. It has been said, for example, that according to Stahl, the product of combustion is simple, and the combustible a compound of the product with imaginary phlogiston—which is false; whereas, according to Lavoisier, the combustible is simple, and the product a compound of the combustible with actual oxygen—which is true. But in this case, as in so many others, everything turns upon the use of the same word in a different sense at different periods of time. When Lavoisier spoke of red lead as being metallic lead combined with oxygen, he meant that the matter or stuff of the red lead consisted of the matter or stuff of lead *plus* the matter or stuff of oxygen. But when the Stahlans spoke of metallic lead being burnt lead combined with phlogiston, they had the same sort of idea of combination in this instance, as others have expressed by saying that the weight of a body is compounded of its matter and its gravity; or that steam is a compound of water and heat; or, to use a yet more Lavoisierian expression, that oxygen gas itself is a compound of the basis of oxygen with caloric. It is not, then, that the one statement, Stahlian or Lavoisierian, is false and the other true, but that both of them are distorted, because incomplete. Chemists nowadays are both Stahlian and Lavoisierian in their notions; or have regard both to energy and matter. But Lavoisierian ideas still interfere very little with our use of the Stahlian language. While we acknowledge that in the act of burning the combustible and the oxygen take equal part, just as in the act of falling the weight and the earth take equal part, yet in our common language we alike disregard the abundant atmosphere and abundant earth as being necessarily understood, and speak only of the energy of the combustible and of the weight, which burn and fall respectively. Whatever may be the fault of language, however, chemists do not omit to superpose the Lavoisierian on the Stahlian notion. They recognise fully that it is by the union of the combustible with oxygen that phlogiston is dissipated in the form of heat; and further, that phlogiston can only be restored to the burnt combustible on condition of separating the combustible from the oxygen with which it has united; just as energy of position can only be restored to a fallen weight on condition of separating it to a distance from the surface on which it has fallen.

That Stahl and his followers regarded phlogiston as a material substance, if they did so regard it, should interfere no more with our recognition of the merit due to their doctrine than the circumstance of Black and Lavoisier regarding caloric as a material substance, if they did so

regard it, should interfere with our recognition of the merit due to the doctrine of latent heat. But though defining phlogiston as the principle or matter of fire, it is not at all clear that the phlogistians considered this matter of fire as constituting a real body or ponderable substance; but rather that they thought and spoke of it as many philosophers nowadays think and speak of the electric fluid and luminiferous ether. The nondescript character, properly ascribable to phlogiston, is indicated by the following quotation taken from Macquer's "Elemens de Chymie Theorique," 1749. It must not, of course, be forgotten that the popular impression as to phlogiston having been conceived by its advocates as a material substance having a negative weight or levity, is erroneous; and is based on an innovation that was introduced during the struggling decadence of the phlogistic theory, and advocated more particularly by Lavoisier's subsequent colleague, Guyton de Morveau, in his "Dissertation sur le Phlogistique, considéré comme Corps grave, et par rapport aux changemens de pesanteur qu'il produit dans les corps auxquels il est uni," 1762. Macquer writes as follows:—

"La matière du soleil, ou de la lumière, le phlogistique, le feu, le soufre-principe, la matière inflammable, sont tous les noms par lesquels on a coutume de désigner l'élément du Feu. Mais il parait qu'on n'a pas fait une distinction assez exacte . . . du nom qu'il mérite véritablement lorsqu'il entre effectivement comme principe dans la composition d'un corps, ou bien lorsqu'il est seul et dans son état naturel. Si on l'envisage sous cette dernière vue, le nom de Feu, de matière du soleil, de la lumière et de la chaleur, lui convient particulièrement. Pour lors, c'est une substance que l'on peut considérer comme composée de particules infiniment petites, qui sont agitées par un mouvement très rapide et continu, par conséquent essentiellement fluide. Cette substance, dont le soleil est comme le réservoir général, s'en émane perpétuellement, et est répandue universellement dans tous les corps que nous connoissons; mais non pas comme principe ou essentielle à leur mixtion, puisqu'on peut les en priver, du moins en grande partie, sans qu'ils souffrent pour cela la moindre décomposition. . . . Cependant les phénomènes que présentent les matières inflammables lorsqu'elles brûlent, nous indiquent qu'elles contiennent réellement la matière du Feu comme un de leurs principes. . . . Examinons donc les propriétés de ce feu fixé, et devenu principe des corps. C'est lui auquel nous donnerons particulièrement le nom de matière inflammable, due soufre principe, ou de phlogistique, pour le distinguer du Feu pur."

Again, much the same thing is to be found in Baumé's "Manuel de Chymie," 1765; as for example:—

"Nous considérons le feu sous deux états différens. Lorsqu'il est pur, isolé, et qu'il ne fait partie d'aucun composé . . . Lorsqu'il est combiné avec d'autres substances, et qu'il fait un des principes constituans des corps composés . . . On n'est pas certain si le feu est pesant. Il y a des expériences pour et contre. . . .

"Pendant la combustion des substances, le feu combiné se réduit en feu élémentaire, et se dissipe à mesure. Le célèbre Boerhaave n'est cependant pas de ce sentiment; il dit que si cela étoit, la quantité de feu élémentaire devrait augmenter à l'infini dans la nature. . . . Mais il est facile de répondre à cette objection, en disant comme on est en droit de la présumer, que le feu élémentaire, dégagé des corps, se combine à mesure avec d'autres substances, et qu'il perd toutes ses propriétés de feu libre, en devenant principe constituant des corps, dans la composition desquels il entre. . . . Le principe dont nous entendons parler ici, est celui que Stahl a nommé *phlogistique*."

In interpreting the above and other phlogistic writings by the light of modern doctrine, it is not meant to attribute to their several authors the precise notion of energy that now prevails. It is contended only that the phlogistians had, in their time, possession of a real truth in nature which, altogether lost sight of in the intermediate

period, has since crystallised out in a definite form. "I trust," said Beccher, "that I have got hold of my pitcher by the right handle." And what he and his followers got hold of and retained so tenaciously, though it may be shiftingly and ignorantly, we now hold to knowingly, definitely, and quantitatively, as part and parcel of the grandest generalisation in science that has ever yet been established.

ON THE EFFECT OF CERTAIN METALLIC SUBSTANCES BESIDES IRON ON CARBONIC OXIDE, INCLUDING SILICON.*

By I. LOWTHIAN BELL.

A DENSE fume is emitted from furnaces smelting the Cleveland ironstone, and this, condensing, lodges in large quantities in the pipes for conducting the gases to the boilers, &c. In the so-called flue-dust zinc is always found, and in most ores there is more or less manganese, occasionally copper, often titanium, and some other metals.

Under the circumstances, it was natural to try the power of metals thus often found associated with iron in its ores, in splitting up CO, to which was added experiments upon others not generally found in connection with that one which it is our more immediate province to examine.

In the following experiments every care was taken to have the CO free from cyanogen, otherwise a carbonaceous deposit, probably paracyanogen, takes place, and to have the metals and their oxides without a trace of iron. In one case, that of copper, in the first trials a minute quantity of carbon was found deposited, which subsequent investigation proved to be caused by a trace of iron being present.

Manganese.—

Dioxide (MnO₂) was obtained by boiling an alkaline permanganate with nitric acid, and drying the precipitate after it was thoroughly washed.

Manganoso-manganic oxide (Mn₃O₄) was got by heating pure MnCO₃ in a current of air until it contained no trace of CO₂. The MnCO₃ was procured free from iron by adding a small quantity of Na₂CO₃ to a solution of manganese, and boiling the resulting turbid liquor until every trace of iron was precipitated by the MnCO₃ thrown down at first. The filtered liquid thus freed from Fe was then precipitated by further addition of Na₂CO₃, and the precipitate thoroughly washed and dried.

These two oxides were exposed to a stream of pure CO with the results given below:—

	Expt. 376.	Expt. 377.	Expt. 378.
	MnO ₂ .	MnO ₂ .	Mn ₃ O ₄ .
Time of exposure ..	4½ hours	6½ hours	10 hours
Temperature—	Below red heat,	Zinc softened,	Zn fused, Sb not.
Loss of weight ..	—	19.6 per ct.	7.1 per ct.
Theoretical loss for reduction to MnO	—	18.4 „	7.0 „
Increase of weight on roasting in oxygen	7.53 per ct.	—	—
Theoretical increase of weight for Mn ₃ O ₄	7.51 „	—	—
Carbon deposited ..	nil	nil	nil

From these trials it seems that MnO₂, at a heat short of redness, is converted by CO into MnO in 4½ hours, and that both MnO₂ and Mn₃O₄ lose oxygen readily at the temperature of melting zinc, both being reduced to MnO.

* From the "Chemical Phenomena of Iron Smelting."

In no case was there a trace of carbon present. It would therefore appear that oxides of Mn are incapable of acting on CO, as Fe does, by separating this gas into C and CO₂, and that no suboxide Mn₂O is formed.

Copper.

Pure copper oxide was got by electrolysis of re-crystallised sulphate, solution in nitric acid, evaporation, and ignition.

Expt. 379.—The oxide of copper was exposed at a temperature of melting zinc to CO for 7 hours, after which its composition was—

Copper		98.1
Oxygen		1.9
C		nil
		100

So that reduction was nearly complete in this time.

Expt. 380.—At a low red heat, oxalic acid gas (equal vols. CO and CO₂) withdrew all the oxygen from oxide of copper. The loss of weight was 20.3 per cent—20.2 per cent being the theoretical equivalent of O. No carbon was precipitated.

Expt. 381.—Pure spongy Cu, obtained by reducing the above oxide in H, was kept in contact with CO for 10 hours, at a temperature of melting zinc. No change of weight, hence no C deposited.

Expt. 382.—Pure spongy Cu, exposed for 2 hours to oxalic acid gas, at a dull red heat, did not alter in weight.

Zinc.

ZnO was obtained by treating pure ZnCl₂ with Na₂CO₃, and igniting the ZnCO₃ obtained—

Expt. 383.—Exposed at temperature of melting zinc to pure CO for 6½ hours. No carbon deposited, nor was there any sensible amount of reduction, the weight of the product not being altered by moistening with NO₃H, and gentle ignition.

Tin.

Stannic oxide obtained by oxidation of block tin by nitric acid.

Expt. 384.—Action same as with ZnO in CO, at temperature of melting zinc. No carbon, nor any appreciable amount of reduction, the weight not altering sensibly by treatment with NO₃H.

Chromium.

Expt. 385.—Anhydrous chromic oxide obtained by igniting potassium anhydro-chromate (bichromate of potash), and washing the product. Had become darker, but contained no carbon, and was in other respects unchanged by exposure to CO for 7½ hours, in lead bath, to about 410° C. (770° F.).

Expt. 386.—Hydrated chromic oxide, got by precipitation of chloride by means of ammonia, was exposed at the same time as the chromic oxide in previous experiment. Original colour bluish-green, changed to bright green. In other respects no change, save that almost the whole of the water of hydration was expelled.

Lead.

Lead oxide got by ignition of crystallised nitrate:—

Expt. 387.—PbO exposed to CO, for 6½ hours, at a temperature of melting zinc. Perfect reduction ensued.

Expt. 388.—PbO, same treatment and same results, at red heat, in 6½ hours. No trace of carbon in either of these experiments.

Nickel.

Re-crystallised nickel nitrate (commercially pure) was boiled with nitric acid, and an excess of ammonia added. This dissolved the precipitated oxide of nickel, but left a trace of Fe₂O₃, which was separated in the usual way. The alkaline solution of the oxide of nickel was evaporated to dryness, and ignited in two portions. Either from the presence of a little adhering nitrate of ammonia, or from differences in the temperature at which ignition was effected, two different oxides were obtained—the one, compact, and nearly corresponding to NiO (Ni 78.7 O 21.3); and the other to Ni₂O₃ (Ni 71.1 O 28.9).

The two oxides of nickel thus obtained had the following composition, arrived at by reducing known weights of each in pure hydrogen.

	Compact Oxide.	Black Oxide.
Ni	77.5	71.2
O	22.5	28.8
	100	100

These two substances were exposed to a current of pure CO in the lead bath arrangement:—

Expt. 389.—Compact oxide. *Expt. 390.*—Black oxide.

Time of exposure, 7½ hours.		Time of exposure, 10 hours.	
Temperature—Zinc melted, Antimony not affected.		Temperature—Zinc melted, Sb not.	
Composition of product.	{ Ni .. 87.2 28.1 O .. 12.2 C .. 0.6 71.9		
	100.0		100.0

In experiment 389 the residual oxygen is just 14.0 per cent of the weight of the total nickel present: this represents an oxide, having almost exactly the composition of Ni₂O (which requires 13.6 to 100 Ni). No nickel, in this case, was dissolved out by iodine; and as iodine was found to attack spongy nickel reduced by hydrogen, with ease, there could have been no metallic nickel present.

It was shown formerly (Experiments 62 to 69), that in several instances where Fe₂O₃ had been imperfectly reduced by CO, the proportion between the iron insoluble in iodine and the residual oxygen was almost exactly that required to form a suboxide, Fe₂O: hence it would appear that nickel and iron are analogous in this respect also, viz., that the suboxides of both are not acted on by iodine and cold water. As will be presently shown, CO₂O, if formed, is acted on thus, the product being, however, not the sesquioxide (as in the case of iron when the hydrated protoxide is thus oxidised), but the protoxide.

In the case of the Ni₂O₃ the carbon and oxygen determinations were faulty, and the sum of both was ascertained by finding the quantity of nickel present in the mass after exposure to CO. The result is such that there must have been a carbon deposition equal to about 250 per cent of the nickel actually present.

In a stream of oxalic acid gas (equal volumes of CO and CO₂) the compact oxide gave the following results:—

	Per cent,
<i>Expt. 391.</i> —O lost in 2½ hours .. at a low red heat, 204°	20.4
Do. 3 " more .. do.	1.1
Do. 3 " " .. do.	0.2
	21.7

<i>Expt. 392.</i> —O lost in 3 hours .. at a bright red heat, 220°	22.0
Do. 2 " more .. do.	0.1
	22.1

The original oxygen present being 22.5 per cent, it appears that a mixture of equivalents of CO and CO₂ has the power, at both these temperatures, almost completely to deoxidise NiO.

Trials were then made to discover the action of the pure spongy metal on pure CO. A portion of the compact oxide was reduced in hydrogen until no more H₂O was evolved. A current of CO was then passed over the metallic Ni thus obtained:—

<i>Expt. 393.</i> —Time of exposure, 5 hours.		<i>Expt. 394.</i> —5 hours.	
Temperature—Melting zinc.		Bright red heat	
Composition of product.	{ Ni .. 99.93 100.0 C .. 0.04 O .. 0.03		
	100.0		100.0

The dissociation, therefore, of the CO at a temperature of melting zinc was very feeble, and at a bright red heat it was nil.

The power of the spongy metal to decompose CO_2 was next made the subject of investigation.

Expt. 395.—At melting zinc no appreciable amount of CO was obtained after 30 minutes' exposure, the metal gaining in weight 0.3 per cent, probably due to traces of moisture and air present.

Expt. 396.—At a low red heat the metal gained 3 per cent of its weight in 90 minutes.

Expt. 397.—At a bright red heat 40 c.c. of gas were obtained after 40 minutes' exposure, which was unabsorbed by potash. It was found to contain 96 per cent of CO.

Expt. 398.—Spongy nickel, at a moderately bright red heat, was unaffected after an exposure of 15 hours to oxalic acid gas (equal vols. of CO and CO_2).

The nickel oxide employed in these experiments might contain some cobalt, but, if so, it was the minutest trace; not the faintest indication of its presence being shown by the very delicate test afforded by the borax bead before the blowpipe.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

ROYAL IRISH ACADEMY.

May 29th, 1871.

At the general meeting of the Academy, the President, the Rev. J. JELLETT, read a paper upon "*The Cultivation of Beet-Root Sugar in Ireland.*"

Six specimens of the white beet, grown at the Model Farm at Glasnevin, had been examined with the Jellett saccharometer. The sliced root was digested with weak alcohol three or four times; the solutions were evaporated and then made up, after having been heated to 180° , to a given bulk with water. This solution was filtered through charcoal, and the first portions rejected as a certain amount of the sugar is absorbed. The sugar present in the beet almost entirely consisted of cane sugar. The following are the results of the six determinations:—

1st.	12.05	per cent
2nd.	9.50	" "
3rd.	12.58	" "
4th.	12.59	" "
5th.	11.62	" "
6th.	12.43	" "

Professor Jellett said that anything over 10 per cent might be considered very good and would pay to work.

Dr. SULLIVAN remarked (in a discussion that followed) that he was very glad to find his statements corroborated, viz., that beet-root could be easily grown in Ireland containing 10 to 12 per cent of sugar. No 2, which contained only about 9 per cent of sugar, had not been earthed up, and this fact is corroborative of a statement that a powerful sun was not necessary to produce saccharine matter in the root. All the other specimens had been earthed up.

Dr. W. SULLIVAN then read a paper "*On the Comparative Chemical Composition of Ancient Bronzes,*" which was in connection with the ethnology, metallurgy, and commerce of the ancient people of Europe.

CORRESPONDENCE.

TECHNICAL EDUCATION FOR THE SONS OF FARMERS.

To the Editor of the Chemical News.

SIR,—By the enclosed extract you will see that I have been anxious to set on foot a scheme cognate to that of Mr. Little, whose plan I was most glad to read in your last number. I should be glad to work with him, and

propose a central committee. By inserting my enclosed letter you will oblige me, and, I think, forward the cause.—I am, &c.,

MARSHALL HALL.

New University Club, May 27, 1871.

"To the Editor of the '*Devizes Gazette.*'"

SIR,—In these days of Educational talk and of School Boards, there is no need of apology for addressing you upon a branch of the subject which receives too little attention, more especially in agricultural districts. Education must begin from above, and work downward. From the squire to the farmer, from the farmer to the labourer; and, again, from the manufacturer to the artisan must be its course. I certainly think that at this present day we are all awakening to the necessity of educating every man according to his trade, and also to the fact that every man has his trade; that the squire's duties should lead him to the study of political economy, of the law, of the natural sciences, and especially those connected with agricultural operations and accounts. The farmer, when without such things as agricultural chemistry and the physiology of plants, is in mediæval darkness; and the labourer, without the discipline of reading, writing, and arithmetic, is without the proper chances either of justly estimating his present position or of availing himself of the chances which may occur of bettering it. As I have said, the upper classes are quickly awakening to the requirements of a rational training for their sons. The next class also; witness the existence of the Royal Agricultural College: but it is for them to pass on the movement, as it were, to those beneath them. But an especially large class, that of farmers of medium and small holdings, can scarcely afford the means to send their lads to College, nor indeed can they always spare the time and labour which would be taken from home. It follows, therefore, that, if possible, a plan should be proposed for bringing at all events an elementary means of instruction in the higher branches of their own occupation within their reach, at such a cost of time and money as need deter none from taking advantage of it. And, premising that there shall exist a good foundation in reading, writing, and arithmetic, I think I can point out how to obtain this object. At the local centres which form the chief markets of the county, such as Salisbury, Devizes, Chippenham, Trowbridge, or such of these and other places as may be shown to be advisable, not merely from their population but from the number of farms around them, let there be established classes to be held on winter afternoons and evenings, first of every thing in bookkeeping, and then in botany, agricultural chemistry, and geology, and the first elements of surveying. There can be no reason why a class should not be held for mechanics, if sufficient in number. Such a work as Goodeve's "*Elements of Mechanism*" would be inestimable to the humblest artisan, and yet within his mastery. The farmer can take up no better book than "*How Crops Grow,*" and "*Church's Laboratory Guide.*" But none of these will be much good without the assistance of a master. And the way in which these classes might be held would be to pay, say two travelling professors, whose duties should be confined to the county, who should hold classes two evenings a week each at three places. This could be done by a very moderate subscription. It is by no means my idea to afford such classes as a species of charity. I think those who use them would ultimately be sufficient in number to pay for them. But not so at starting, and perhaps a subscription in aid may at all times be useful for proper development of my scheme. There can be no doubt that landlords subscribing will get their money back again through the class of tenants produced in a few years. Finally, these classes would always be an invaluable preparation for the College at Cirencester, and for others of the higher educational institutions. I need not

say that I hope to subscribe myself, and if ever a laboratory is established, say in Devizes, I shall hope to assist in the plain fitting out that will be requisite. I will also contribute to the educational library which will be necessary. At the approaching Quarter Sessions let me ask my brother landlords and my friends the farmers to talk these matters over. I beg those who kindly wish to assist to communicate with me, especially as to forming a private committee for consideration.—MARSHALL HALL, Brighton, Dec. 27, 1870."

MISCELLANEOUS.

Cambridge Local Examinations.—At the meeting presided over the other day by Lord Houghton, at the London University, it was shown that the percentage of those who passed this year, both of boys and girls, had decreased in every department. Of thirty-two juniors from the City of London, four took honours, thirteen passed, and fifteen failed. In that most popular of scientific subjects among the seniors, chemistry, two only passed, out of seventeen presented, one from the Proprietary School, Gravesend, taught by the Professor of Chemistry at the Birkbeck Institution, and one from Denbigh. The examiners declared that "many had come up to be examined on subjects of which they literally knew nothing!"—*City Press*.

The North Austrian Industrial Association.—We have been favoured with a paper from this Association, of which the following is a condensed summary:—It having been found that exhibitors at all the exhibitions hitherto held, and also many of the juries, expressed a well-founded dissatisfaction with the system of giving prizes, the industrial association above-mentioned has adopted the proposal of one of its members, M. F. Ritter von Wertheim, to request all who feel interested in this question to try to reply to the following query, which is put as a prize essay:—"In what manner are to be avoided, or how and by what simple and efficient means are to be improved, the methods of granting and distributing prizes hitherto pursued at exhibitions, at the Great Exhibition which is to take place at Vienna in the year 1873." For the three best essays on this subject, the North Austrian Industrial Association intends to give one of its great gold and two great silver medals, presented for this purpose by M. F. Ritter von Wertheim, upon the following conditions:—The writer or author is not to content himself with simple suggestions, but he should, even though this be done briefly, criticise and expose the advantage as well as the defects of the methods of granting and giving prizes as hitherto pursued at public, general, and other industrial exhibitions, and next propose his plan of an improved method. The essays must be sent in not later than the end of October next, and are to be provided with a motto, and with a sealed note bearing on the outside cover the same motto, and inside the author's name. The manuscripts of the essay remain the property of those to whom the medals shall be given, but the North Austrian Industrial Association (Der N. O. Gewerbe Verein), reserves to itself the right of printing and publishing the essays in its own Transactions. The manuscripts (to be sent carriage or postage paid, to the address of Herr C. V. Scherzer, President of the Association at Vienna) will not be returned, but the essays may be taken back by the authors from the office of the Association. The jury to consider the essays will be appointed by the Association; the medals will be awarded at the General Annual Meeting of the Association in December next. The names of the successful authors of the essays will be made public in all German and, as far as possible, all other European and American newspapers.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Polytechnisches Journal von Dingler, second number for April, 1871.

This number contains the following original papers and memoirs bearing upon chemistry and collateral sciences:—

Improved Copper-Zinc Battery.—L. Kohlfürst.—The arrangement alluded to in this paper cannot be described without reference to the woodcuts added to it.

Reduction of Chloride of Silver in the Moist Way.—Dr. Gräber.—This paper contains the detailed description of the reduction of chloride of silver dissolved in ammonia by means of metallic zinc, which process, according to the author, succeeds very well, and yields a silver of greater purity than is obtained by the process for reduction of silver by the moist way now in use, provided the operation be carried on in closed wide-mouthed stoppered bottles. The silver, after complete reduction (and this has to be tested for by means of a drop of the ammoniacal fluid being put into some hydrochloric acid), is first thoroughly washed with concentrated hydrochloric acid, next with water, and, lastly, for some moments with dilute ammonia, and then again with distilled water, and provided the zinc be used in large lumps thick enough to admit of being readily removed from the spongy silver. It is clear that this method of reduction involves the use of a considerable quantity of ammonia; but this, the author states, can in great measure be recovered by distillation.

Regeneration of Waste Silver Solutions used in Photography.—Dr. Gräber.—After first referring to the generally applied and well-known means now in use for this purpose, the author states that the best plan to treat these solutions is the following:—The solutions are boiled either in a porcelain basin or glass flask, and while boiling there is added to them recently precipitated, well washed, and moist oxide of silver, the boiling being continued for some time. The liquid is next filtered, and then evaporated to dryness, the heat being increased to fusion, so as to destroy ammoniacal salts; the residue is pure nitrate of silver. The sediment on the filter contains some oxide of silver, which must be added in excess; and, therefore, in order not to lose that, the filter is preserved, and the contents worked up at a subsequent operation. The nitrate of silver thus obtained is, by practical photographers, pronounced to be of excellent quality.

Theoretical Estimation of the Value of Various Fire-Clays.—Dr. C. Bischof.—The first portion of a lengthy monograph on this subject, which, however valuable the contents, does not admit of any useful abstraction.

Quantitative Estimation of Nitric Acid.—Dr. A. Wagner.—This method is based upon the fact that when saltpetre, or any other nitrate, is ignited, access of air being excluded, with an excess of oxide of chromium and carbonate of soda, the nitric acid oxidises the chromic oxide according to the formula $\text{Cr}_2\text{O}_3 + \text{NO}_2 = 2\text{CrO}_3 + \text{NO}$. 76.4 parts, by weight, of oxide of chromium are oxidised to chromic acid by 54 parts of nitric acid, or of r of chromic oxide by 0.7668 of nitric acid. The operation is performed by taking from 0.3 to 0.4 grm. of the nitrate, mixing it intimately with 3 grms. of chromic oxide and 1 grm. of carbonate of soda, introducing this mixture into a hard German glass combustion-tube, one end of which is drawn out, and a vulcanised india-rubber tube attached to it, which is made to dip for about a quarter of an inch into water, while to the other open end, by means of a cork and glass tube bent at right angles, an apparatus is fitted for the evolution of carbonic acid gas, which is made to pass through the tube before igniting it, and kept passing through all the time until the tube is quite cool again after ignition. The contents of the tube are placed in warm water, and after filtration the chromic acid is estimated by Rose's method. This process of estimating nitric acid, having been tested by the author with various nitrates, has been found to yield very accurate results.

Industrial Manufacture of Treacle and Dry Sugar from Starch.—C. Krütke.—A lengthy practical treatise on this subject.

Annalen der Chemie und Pharmacie (Supplementband viii.), No. 1, 1871.

This number contains the following original papers and memoirs:—

Occurrence of the Ammoniacal-Magnesian Sulphate in the Lagoons of Tuscany.—Dr. O. Popp.—This essay contains the account of a series of investigations made by the author on the constituents of the boric acid-producing lagoons of Tuscany. The salt alluded to above does not occur to the same quantity in the water of all these lagoons, since that of those producing boric acid in the purest and largest quantity is either not at all, or only slightly, impregnated with the ammoniacal-magnesian sulphate, which is found in a pure state

in the lagoons of Sasso and Aqua Viva. The re-crystallised salt was found to consist, in 100 parts, of —NH_3 , 9.355; MgO , 11.043; 2SO_3 , 44.410; $7\text{H}_2\text{O}$, 35.127;—total, 99.935. Formula—

Formation of Boracic Acid in the Fumaroles of Tuscany.—Dr. O. Popp.—This memoir records, in the first place, the various theories and hypotheses which have been hitherto published for the purpose of explaining the presence, origin, and formation of boracic acid in the active volcanic formation of Tuscany; while, secondly, the author brings forward some experiments tending to explain the formation of boracic acid by the decomposition of boracic minerals under the influence of various reactions which may be supposed to take place aided by the high temperature of the locality, as called forth by volcanic action.

Cumaric Acid, Hydrocumarine, and Hydrocumaric Acid.—M. C. Zwenger.—After describing at length the preparation of cumaric acid from cumarine by the action of a very concentrated solution of caustic potassa, the author states that the purified acid is difficultly soluble in cold, somewhat more readily in boiling, water, from which it is deposited in anhydrous needle-shaped crystals. The acid is more readily soluble in alcohol and ether; the solutions exhibit a strongly acid reaction to test-paper, and decompose alkaline and other carbonates. Cumaric acid fuses at 195° ; by dry distillation it yields chiefly phenol; on being fused with caustic potassa, hydrogen is given off and salicylate and acetate of potassa formed. The formula of this acid is $\text{C}_9\text{H}_6\text{O}_4$. Next follows a detailed description of the salts of this acid, and a discussion on the cumarine contained in the *Trifolium repens*, and in the so-called *fahanitea*; it appears that in these vegetables cumaric acid is also present. Hydrocumaric acid is obtained, along with other substances, by treating an aqueous solution of excess of cumarine with sodium amalgam. The new acid is a crystalline body, scarcely soluble in water, but more readily so in alcohol and ether; formula, $\text{C}_{10}\text{H}_{10}\text{O}_4$. By the elimination of two molecules of water, hydrocumaric acid is converted into hydrocumarine, $\text{C}_{10}\text{H}_{10}\text{O}_3$, a solid crystalline body, almost insoluble in water, alcohol, and ether, and fusing at 222° .

Molecular Weight of some Protoxides.—Dr. A. Ladenburg.—This monograph contains the following sections:—General review; protoxides of iron, manganese, and chromium; tin compounds.

Schiel's Chloral-Uric Acid.—Dr. N. Lubavin.—The main result of this paper is to prove that the acid alluded to, described by M. Schiel (*Ann. Chem. Pharm.*, vol. cxii., p. 78, 1859), and obtained by that author by the action of an aqueous solution of chlorous acid upon uric acid, is not a chemical compound at all, but a mixture of parabanic acid with chloride of ammonium; while the author of this paper also found that, by the action of chlorous acid upon uric acid, intermediate, but unstable, oxidation compounds were formed.

Derivatives from Anethol.—Dr. A. Ladenburg.—After referring at length to his former researches, and also those of other chemists on this subject, the author describes the mode of preparation of anol from anethol by the action of fused caustic potassa. The new compound (anol) $\text{C}_{10}\text{H}_{10}\text{O}$, is soluble in alcohol, ether, chloroform, and boiling water; the substance is very prone to decomposition, and, owing to the small quantity obtained, no derivatives of this body were prepared. The lengthy essay further treats on the action of PCl_5 and bromine upon anethol.

Researches on Vanadium.—Dr. H. E. Roscoe.—The third part of this lengthy monograph, divided into the following sections:—Bromides of vanadium; vanadium and iodine; salts of vanadic acid; artificially-made vanadinite.

Second Axiom of the Mechanical Theory of Heat, and its Application to some Phenomena of Decomposition.—Dr. A. Horstmann.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 7, 1871.

This number contains the following original papers and memoirs:—

Bromal and the By-Products obtained in its Preparation.—Dr. L. Schüller.—The author, while preparing hydrate of bromal on the large scale by causing the vapours of bromine to pass into alcohol, care being taken to avoid an excess of the haloid, and thereby preventing the formation of bromated bromethyls, studied the substances resulting from this reaction by first submitting the raw product to distillation in a steam-bath, and next employing a sand-bath. By the steam-bath heat some bromide of ethyl, acetic ether, and solution of hydrobromic acid were driven off; while, by further heating, three different groups of bodies were obtained, viz.:—At from 100° to 130° , chiefly hydrated bromhydric acid; at from 165° to 180° , bromal and an oily substance insoluble in water; above 180° , some substances boiling with partial decomposition. From the distillate which came over at between 165° and 180° , bromal was separated by the admixture of water, and the hydrate of bromal obtained in a pure state by re-crystallisation. Bromal boils, without decomposition, at 173° , and is not congealed at -20° . The hydrate of bromal fuses at 53.5° , cannot be distilled without decomposition, being converted into water and bromal, which latter, on being mixed with perfectly absolute alcohol, yields a bromal-alcoholate, a solid crystalline body, fusing at 44° , difficultly soluble in water, but readily so in alcohol and ether; on being submitted to distillation it is converted into alcohol and bromal. The formula of this alcoholate of bromal is $\text{C}_3\text{Br}_2\text{OH} + \text{C}_2\text{H}_5\text{O}$. A large portion of the further contents of this memoir is devoted to exhaustive researches on bibrom- and tribrom-acetic acid, and compounds and derivatives thereof.

Action of Phosphuretted Hydrogen upon the Iodides of Methyl and Ethyl.—Dr. A. W. Hofmann.—This very lengthy essay contains the account of a series of researches instituted by the author, in continuation of former experiments, on the preparation of phosphines. The essay, which contains the experiments in the methyl and ethyl series, is not well suited for useful abstraction.

Coal-Tar Cresols.—Dr. H. L. Buff.—Upon a portion of creosote boiling at from 204° to 205° , the author has caused chloride of benzoyl to act, thereby obtaining a solid and a liquid body. The former, a crystalline substance, fuses at 70° , and is, as regards its properties, identical with the benzoate of para-kresol obtained by MM. Latschinoff and A. Engelhardt; the liquid cresol is perfectly colourless, boils at 205° , and is stated by the author to be a para-kresol.

Some Combinations of Tolan.—Drs. Limpricht and Schwanert.—This is a preliminary notice of some researches, not yet finished on the action of chlorine compounds and bromine upon tolan, which yields, it appears, several isomeric chlorides and bromides.

New Compounds of the Camphor Series.—Dr. I. Kachler.—This paper, a fragment of a large essay the author intends to publish, contains the record of some researches on the action of nitric acid upon camphor. It appears that not only camphoric and camphresic acids are formed, but also a fluid combination of camphor and nitric acid—a nitrate of camphor—and another peculiar acid. The nitrate of camphor, $2(\text{C}_{10}\text{H}_{16}\text{O}) \cdot \text{N}_2\text{O}_3$, is a rather unstable, liquid, oily compound, instantaneously decomposed by water, metals, and their oxides, ammonia, aniline, and phenol, but soluble, without decomposition, in alcohol and ether.

Thio-Aniline and Thio-Toluidine.—V. Merz and W. Weith.—This exhaustive and very lengthy monograph is not well suited for any useful abstraction.

Some of the Hydrocarbons of the Marsh Gas Series.—C. Schorlemmer.—The author gives a series of formulae of hydrocarbons prepared by him, and the boiling-points of these substances, all of which are normal—that is to say, that the carbon-atoms are united in a simple manner.

Contribution to our Knowledge on Ditolyles.—Dr. Th. Zincke.—This paper, illustrated with woodcuts, strictly belongs to crystallography.

Researches on Valeraldehyde.—Dr. A. Schröder.—This essay contains the following sections:—Preparation and properties of valeraldehyde; action of chlorine upon valeraldehyde; sulpho-valeraldehyde and seleno-valeraldehyde.

Researches on the Sulphuretted Urea.—A. Arzruni.—The author describes, at great length, the mode of preparation of a sulphurea from amido-benzoic acid. The new body, $\text{C}_8\text{H}_8\text{N}_2\text{O}_2\text{S}$, named monoxy-benzoyl-sulpho urea, is insoluble in cold water, alcohol, and ether, but soluble in boiling water and alcohol. On being heated by itself, this new compound is decomposed, giving off sulphuretted hydrogen, and yielding oxybenzoyl-urea, $\text{C}_8\text{H}_8\text{N}_2\text{O}_2$. The relation which the monoxy-benzoyl-sulpho urea bears to other already known similar compounds is set forth by the following formulae:—Monoxy-benzoyl-sulpho urea—

dioxy-benzoyl-sulpho urea—

monoxy-benzoyl-phenyl-sulpho urea—

Annales des Mines, No. 4, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

New Process for the Treatment of Gold and Silver Orea.—L. E. Rivot.—This very valuable monograph is divided into the following chapters:—Introduction; auriferous veins and lodes; argentiferous veins and lodes; amalgamation processes; laboratory experiments, conducted by MM. Regnault and Cumege; first series of experiments on the action of steam upon simple native and artificially-prepared sulphurets, and upon complex sulphurets; action of super-heated steam upon these and other similar substances; combined action of super-heated steam and oxide of iron, or roasted pyrites mixed with the substances just alluded to; experiments on the large scale made in California; laboratory experiments on amalgamation and other metallurgical operations; observations on amalgamation, and the influence thereupon of oils, lime, and metals; metallurgical methods and apparatus. The essay is illustrated by a series of engravings.

Condensed Report of the Labours Performed at the Departmental Chemical Laboratory established at Mézières (Ardennes).—E. Nivoit and M. Létrange.—This paper contains, among other particulars, a series of analyses of phosphatic nodules (so-called coprolites) found in various localities of this part of France. It appears that the quantity of phosphoric acid contained in these nodules averages 18, does not exceed 22, and not fall below 13 per cent. Average composition of the metal of an old bell of Mézières, in 100 parts—Tin, 20.91; lead, 2.74; zinc, a trace; copper, 76.35. Cadmia from a blast furnace was found to consist, in 100 parts, of—Oxide of

zinc, 89.10; oxide of lead, 59.1; oxide of iron and alumina, 1.90; lime, 0.97; sulphuric acid, 0.13; silica, 0.56;—total, 98.57.

Memoir on the Principal Sites of the Mineral Lodes and Veins of Saxony and Northern Bohemia.—MM. Lévy and Choulette.—This essay is a very valuable contribution to the knowledge of the metallurgically-workable minerals in the countries named.

Report on the Official Inquiry on the Condition of the Miners and Factory Workers in Belgium.—M. Demongot.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, vol. xv., No. 4, 1870.

This number does not contain any papers relating to chemistry or allied sciences.

Vol. xv., No. 5, 1871.

The only papers relating to physical sciences in this number are:—

Preliminary Notice on the Application of Secondary or Polarisation Batteries to Electro-Magnetic Motors.—Professor Jacobi.—The author first enters at length into theoretical discussions on the various polarisation batteries, or substitutes therefor, proposed at various times by different physicists, more especially in England and France. The author next describes a polarisation battery made of leaden plates put into sulphuric acid (1.3 sp. gr.), and each having 900 centimetres' surface, the troughs (6.5 centimetres long by 6.3 wide and 13.6 high) being made of gutta percha. Of this kind of galvanic element the author employs fifty, and charges them by the aid of four large-sized Grove's or Bunsen's cells.

Micrographical Researches.—Dr. A. Stuart.—This paper, illustrated by woodcuts, contains a detailed description of a new and ingeniously-devised plan for the measurement of objects seen under the microscope.

Journal für Gasbeleuchtung und Wasserversorgung, No. 7, 1871.

The only matter relating to chemistry and collateral sciences met with in this paper is—

Oxygen, its Occurrence, Preparation, and Application for Illuminating Purposes; and on a New Method of Oxygen Illumination.—Dr. J. Phillips.—This periodical also contains a brief review of the work of the author just named, and recently published by him in German at Berlin. It appears that the carboxygen lamp invented by the author, and obtainable from the firm of Georg Berghausen, at Cologne, is, in every respect, a great success. The lamp need not be fed with pure oxygen, the author having found that an artificial air containing 50 per cent of oxygen yields light of the same intensity as pure oxygen. The lamp consumes, per hour, 4.3 English cubic feet of the gas just alluded to under a pressure of 30 mm., and with a consumption of 20 grms. of a fluid the nature of which is not explained. The author's pamphlet is illustrated with woodcuts and two lithographic plates.

Journal für Praktische Chemie, No. 5, 1871.

The greater portion of this number is filled with the continuation and end of the lengthy essay—

Contribution to our Knowledge of the Geminated (Gepaarten) Compounds of the Pentatomic Nitrogen.—C. W. Blomstrand.—See CHEMICAL NEWS, vol. xxiii., p. 597.

The only other paper, on the—

Products of the Acid Fermentation of Wheaten Bran.—A. Freund.—Contains the very detailed description of a series of experiments made by the author with the view of thoroughly investigating the various products of the acid fermentation of wheaten bran. The main results arrived at are, that this fermentation mainly produces lactic acid, but, in addition thereto, formic, acetic, butyric, and capronic acids are formed; but neither propionic nor valerianic acids are generated. The author states that he is engaged in making further researches on this subject, taking care to cause the process of fermentation to proceed at varying temperatures, in order also to find out, if possible, a more expeditious and advantageous method of preparing propionic acid, instead of its preparation from cyanide of ethyl.

NOTES AND QUERIES.

Nitrobenzol.—Will any of your readers kindly inform me how best and safely to distil nitrobenzol so as to obtain it colourless?—MIRABANE.

Removing Sulphur from Coke.—(Reply to "R.")—You will find in Ronalds and Richardson's "Chemical Technology," vol. i., part i., p. 124, every information you desire on the subject; the quotation in our Notes and Queries would occupy too much space. The work referred to was published in 1855 by Messrs. Baillière. Consult, also, "Abridgements of all Specifications of Patented Inventions" (No. 30, Preparation and Combustion of Fuel), published by the Commissioners of Patents.

Removing Sulphur from Coke.—In reply to your correspondent, "R.," in Notes and Queries of your last issue, Professor Calvert patented, in 1851, a process for purifying coke similar to that described

by him, the only difference being that the salt was mixed with the coal before coking in a solid form, instead of as brine. This process failed for the reason that, by the decomposition of the salt, sulphate of soda, and some other combinations of the sulphur and the sodium were formed (the chlorine escaping principally as hydrochloric acid probably), and by these means the sulphur, instead of being removed, was fixed in the coke. I am superintending the working out of a process, patented by my brother in 1868, for the removal of sulphur and phosphorus from coke and ores, and have obtained some good results from it. Calcination, or coking with common salt, is a feature in this process, but the ore and the coke are washed in water after the ignition. The compounds formed during the ignition being soluble in water, this effectually removes them.—F. J. ROWAN, Atlas Steel Works, Glasgow.

Alteration of Arsenious Acid.—Can any of your readers tell me if it is known as a fact that arsenite of potash in solution is liable to alteration on keeping? Eight years ago, I made a solution, containing 139.6 grs. in a decigallon, for chlorine testing for a friend—a paper maker. Half the quantity has stood for some years in a stoppered bottle, half full; and, on testing it yesterday against a freshly-prepared solution, I found a discrepancy of $5\frac{1}{2}$ —the As_2O_3 had partly already become As_2O_5 . If this is not a known fact, it may be useful to many of your subscribers to learn that, unless sufficiently freshly made, the arsenious acid solution is not an entirely reliable test. Though, regarding the amount of error introduced, and the time the solution had been kept, I should say that the error in one year would be hardly sufficient to impair its usefulness as a manufacturer's test.—JOHN S. LINFORD.

Welding of Cast-Steel and Iron.—In a well-known American paper, we find a notice on the subject of welding cast-steel together, which briefly comes to the following, and might, perhaps, be tried in the welding of steel to iron. The author, evidently a practical man, states that he first upsets the two ends that are to be welded considerably larger than the welded part is to be when hammered down to the proper size; next, split one of the ends of the bar a little deeper than the bar is thick, draw out the ends of the lips and narrow them up at the points, and draw out the end to be welded into this into a blunt wedge shape, narrowing the end also; next make, with a cold chisel, a cut on one side of the wedge-shaped end, in order to prevent it from slipping out when sticking them together, and afterwards heat the two ends that are to be united to a cherry-red heat, using common borax; unite them in the usual way, driving them together endwise, then, closing down the two lips with the hammer at a bright cherry-red heat, they will stick together; then put on plenty of borax, and heat in a charcoal fire to a point just above a bright cherry-red heat, but not to a sparkling heat as in welding iron.

MEETINGS FOR THE WEEK.

- MONDAY, June 5th.—Royal Institution, 2. General Monthly Meeting.
TUESDAY, 6th.—Royal Institution, 3. Rev. Prof. Haughton. "On the Principle of Least Action in Nature."
Zoological, 9.
WEDNESDAY, 7th.—Microscopical, 8.
Geological, 8.
London Institution, 2. Distribution of Prizes and Certificates by the President, Thomas Baring, Esq., M.P.
THURSDAY, 8th.—Royal Institution, 3. Prof. Tyndall, LL.D., F.R.S., "On Sound."
Royal Society Club, 6.
FRIDAY, 9th.—Royal Institution, 9. Prof. Tyndall, LL.D., F.R.S., "On Dust and Smoke."
Astronomical, 8.
Quekett Microscopical Club, 8.
SATURDAY, 10th.—Royal Institution, 3. J. N. Lockyer, Esq., F.R.S., "On the Instruments Used in Modern Astronomy."
Quekett Microscopical Club. Excursion to Homerton; to meet at Broad Street Station at 2 p.m.

TO CORRESPONDENTS.

ERRATA.—In No. 600, p. 249, line 18 from bottom of left-hand column, for " $Tl_2PtCl_6 \cdot 6CO_2IO_4$," read " $Tl_2PtCl_6 \cdot 6CO_2IO_4$." Page 250, line 5 from top of left-hand column, for "that no combination" read "that combination."
Page 250, line 2 from top of right-hand column, for "falls" read "fills."

A Subscriber.—A work on the subject, by the Editor, is in the press; it will be duly announced.

Subscriber.—The product cannot, we believe, be obtained in England.
A. Ridge.—We have received the white carbonate; what are our correspondent's wishes concerning it?

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

On Friday next, dem: 8vo., with 42 woodcuts, price 14s.

The Antiseptic System: A Treatise on Carbolic Acid and its Compounds, with an Inquiry into the Germ-Theories of Putrefaction, Fermentation, and Infection, the Theory and Practice of Disinfection, and the Employment of Antiseptics in Practical Medicine and Surgery. By A. E. SANSON, M.D., London, M.R.C.P.

London: HENRY GILLMAN, Boy Court, Ludgate Hill, E.C.

Now ready, price 6d.

Notes of Professor Odling's Juvenile Lectures on BURNING AND UNBURNING, delivered at the Royal Institution of Great Britain, Christmas, 1870-71.

London CHEMICAL NEWS Office, Boy Court, Ludgate Hill, E.C.

NEW WORK BY RICHARD PROCTOR, B.A.

In One Volume, crown 8vo., price 7s. 6d. cloth,

Light Science for Leisure Hours; a Series of Familiar Essays on Scientific Subjects, Natural Phenomena, &c. By R. A. PROCTOR, B.A., F.R.A.S., Author of "Saturn and its System," "Other Worlds than Ours," "The Sun," &c.

Longmans, Green, and Co., Paternoster Row.

Royal 8vo., pp. 388, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling,

A Concise View of the Law connected with Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentee's Manual."

London: Longmans, Green and Co., Paternoster Row.

Just published, price 1s. 9d., cloth, 100 pp.,

The Chemical Note Book. For the use of Students in Practical Chemistry.

S. Deacon, Medical Bookseller, 30, King Street, Borough, close to Guy's Hospital.

All Medical Works for the use of Students at a liberal discount for cash.

*. A large Stock of Note and Report-Books.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gunpowder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane Tower Street, E.C. who hold stock ready for delivery.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY AND NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily. Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

ST. PAUL'S, STONY STRATFORD.

A Special Department in connection with this

Institution has been formed under the direction of Thomas Jones, Esq., F.G.S., F.R.A.S., Associate of the Royal School of Mines, for the purpose of providing systematic Instruction in Science.

The courses of study include Chemistry and Chemical Analysis, Geology, Physics, and Physiology.

Pupils in this department may also receive instruction in General Knowledge.

Advanced Pupils are specially prepared for Science Scholarships at the Universities and for other Examinations.

The charges for Board and Instruction amount to £60 a year.

Further information may be obtained by applying to the Reverend the Warden.

North London School of Chemistry, Phar-

macy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual ENCOURAGEMENTS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{2}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{2}$ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

Royal Polytechnic.—Whitsun Holidays.—

Professor Pepper's "Trip to the Western Highlands of Ireland;" grand Scenery and Irish Songs by Miss Barth.—Great Revival of Henry Russell's Songs, under his personal kind superintendence, with Grand Scenic and Optical Effects. Vocalist, Mr. Plumpton.—J. L. King, Esq., on "Muscle and Muscular Power," illustrated by Herr Wilho, the wonderful Contortionist and Imitator of Birds and Animals.—Re-engagement of E. D. Davies, the Premier Ventriloquist.—The Ghost and other Entertainments as usual.—Admission One Shilling. Open from 12 to 5, and 7 to 10.

THE CHEMICAL NEWS.

VOL. XXIII. No. 602.

NOTE ON THE SPECTRUM OF URANUS AND THE SPECTRUM OF COMET I., 1871.*

By WILLIAM HUGGINS, LL.D., D.C.L., V.P.R.S.

IN the paper "On the Spectra of some of the Fixed Stars,"† presented conjointly by Dr. Miller and myself to the Royal Society in 1864, we gave the results of our observations of the spectra of the planets Venus, Mars, Jupiter, and Saturn; but we found the light from Uranus and Neptune too faint to be satisfactorily examined with the spectroscop.

By means of the equatorial refractor of 15 inches aperture, by Messrs. Grubb and Son, recently placed in my hands by the Royal Society, I have succeeded in making the observations described in this paper of the remarkable spectrum which is afforded by the light of the planet Uranus.

It should be stated that the spectrum of Uranus was observed by Father Secchi in 1869.‡ He says—"Le jaune y fait complètement défaut. Dans le vert et dans le bleu, il y a deux raies très larges et très naires." He represents the band in the blue as less refrangible than F, and the one in the green as near E.

The spectrum of Uranus, as it appears in my instrument, is represented in the accompanying diagram. The narrow spectrum placed above that of Uranus gives the

relative positions of the principal solar lines, and of the two strongest absorption-bands produced by our atmosphere, namely, the group of lines a little more refrangible than D, and the group which occurs about midway from C to D. The scale placed above gives wave-lengths in millionths of a millimetre.

The spectrum of Uranus is continuous, without any part being wanting, as far as the feebleness of its light permits it to be traced, which is from about C to about G.

On account of the small amount of light received from this planet, I was not able to use a slit sufficiently narrow to bring out the Fraunhofer lines. The positions of the bands produced by planetary absorption, which are broad and strong in comparison with the solar lines, were determined by the micrometer and by direct comparison with the spectra of terrestrial substances.

The spectroscop was furnished with one prism of dense flint-glass, having a refracting-angle of 60°, an observing telescope magnifying 5½ diameters, and a collimator of 5

inches focal length. A cylindrical lens was used to increase the breadth of the spectrum.

The remarkable absorption taking place at Uranus shows itself in six strong lines, which are drawn in the diagram. The least refrangible of these lines occurs in a faint part of the spectrum, and could not be measured. Its position was estimated only, and on this account it is represented in the diagram by a dotted line. The positions of the other lines were obtained by micrometrical measures on different nights. The strongest of the lines is that which has a wave-length of about 544 millionths of a millimetre.

The band at 572 of the scale is nearly as broad but not so dark; the one a little less refrangible than D is narrower than the others.

The measures taken of the most refrangible band showed that it was at or very near the position of F in the solar spectrum. The light from a tube containing rarefied hydrogen, rendered luminous by the induction-spark was then compared directly with that of Uranus. The band in the planet's spectrum appeared to be coincident with the bright line of hydrogen.

Three of the bands were shown by the micrometer not to differ greatly in position from some of the bright lines of the spectrum of air. A direct comparison was made when the principal bright lines were found to have the positions, relatively to the lines of planetary absorption, which are shown in the diagram. The band which has a wave-length of about 572 millionths of a millimetre is less refrangible than the double line of nitrogen which occurs near it. The two planetary bands at 595 and 618 of the scale appeared very nearly coincident with bright lines of air. The faintness of the planet's spectrum did not permit of certainty on this point; I suspected that the planetary lines are, in a small degree, less refrangible. There is no strong line in the spectrum of Uranus in the position of the strongest of the lines of air, namely, the double line of nitrogen.

As carbonic acid gas might be considered, without much improbability, to be a constituent of the atmosphere of Uranus, I took measures with the same spectroscop of the principal groups of bright lines which present themselves when the induction-spark is passed through this gas. The result was to show that the bands of Uranus cannot be ascribed to the absorption of this gas.

There is no absorption-band at the position of the line of sodium. It will be seen by a reference to the

diagram that there are no lines in the spectrum of Uranus at the positions of the principal groups produced by the absorption of the earth's atmosphere.

Spectrum of Comet I., 1871.

On April 7 a faint comet was discovered by Dr. Winnecke. I observed the comet on April 13 and May 2. On both days the comet was exceedingly faint, and on May 2 it was rendered more difficult to observe by the light of the moon and a faint haze in the atmosphere. It presented the appearance of a small faint coma, with an extension in the direction from the sun.

When observed in the spectroscop, I could detect the light of the coma to consist almost entirely of three bright bands.

A fair measure was obtained of the centre of the middle band, which was the brightest; it gives for this band a wave-length of about 510 millionths of a millimetre. I was not able to do more than estimate roughly the position of the less refrangible band. The result gives 545 millionths. The third band was situated at about the same distance from the middle band on the more refrangible side.

It would appear that this comet is similar in constitution to the comets which I examined in 1868.*

ON A

NEW METHOD OF PREPARING SUPERSATURATED SALINE SOLUTIONS.

By L. C. De COPPET, Ph.D.

IN 1868-69 I made, in the laboratory of the Royal College of Chemistry, a series of experiments on supersaturated solutions, of which the following are some of the results.*

Supersaturated solutions of sodic sulphate are usually prepared by cooling, in closed vessels, solutions saturated at a higher temperature.

I have found that so-called supersaturated solutions of sodic sulphate may be prepared at ordinary temperatures by simply dissolving the anhydrous salt in cold water.

To ensure the success of the experiment it is necessary to protect the solution from contact with the dust floating in the atmosphere. The anhydrous salt itself must be rendered "inactive" if for any length of time it has been exposed to the air. This is done by heating it to a temperature above 33° C. (I have found 40° C. sufficient, but it is safer to heat as high as 100° or 200°) and cooling in a closed vessel.

The salt must be added to the water in small quantities at a time, first, because the heat evolved by its contact with the water would otherwise be sufficient to raise the temperature several degrees, and it might be objected that this was the cause of the supersaturation; secondly, because the salt, if added all at once, forms a hard cake which dissolves but slowly.

The greater part of my experiments were conducted in the following way:—The salt was put into a short wide tube sealed at one end, drawn out and bent at right angles at the other, so as to pass, together with a thermometer, through the neck of a small flask. When this tube containing the anhydrous salt had been heated and cooled in order to render the salt "inactive," and the flask well washed and half-filled with cold water, the narrow end of the tube was introduced into the flask (not so far as to touch the water), and the space left between it, the thermometer, and the neck of the flask filled with cotton-wool. By gently shaking the tube, the salt would fall into the water, a very little at a time, and dissolve, without sensible rise of temperature, in much larger quantities than the ordinary crystallised salt ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$).

If the flask is placed in a large water-bath, the temperature may be kept very nearly constant throughout the experiment.

On one occasion, the temperature of the water at the beginning of the experiment was 13.5° C. Salt was added, and the flask often shaken, to hasten the solution, without being withdrawn from the water-bath. In two hours the temperature had slowly risen to 14° , and it being then evident that no more salt was dissolved—in other words, that the solution was saturated with anhydrous sodic sulphate—a portion of the perfectly clear menstruum was poured into several clean dry flasks, each provided with a cork. Two of these flasks I succeeded in weighing before the solution crystallised, and found both times that the strength of the solution was 35.8 parts of anhydrous sodic sulphate (Na_2SO_4) to 100 water. The concentration of this solution was, therefore, nearly three times that of the ordinary solution saturated with the normal salt—

which, at 14° C., contains 12.4 parts anhydrous salt to 100 water.

Another experiment showed the solubility of anhydrous sodic sulphate at 21° C. to be very nearly 52.7 parts of Na_2SO_4 to 100 water; the solubility of the hydrate—

at the same temperature is but 20.9 parts anhydrous salt to 100 water.

These experiments show that an ordinary saturated solution of anhydrous sodic sulphate is identical with what is commonly called a supersaturated solution. Of course I do not mean to imply by the words "solution of anhydrous sodic sulphate" that the salt in the solution is in the anhydrous state.

It is now very generally admitted that crystals of the 10-atom salt ($\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$) always bring about the solidification of a supersaturated solution of sodic sulphate. Among the many who of late years have investigated the subject, Mr. Tomlinson is, I believe, the only one who holds the opposite view.

Completely effloresced Glauber's salt, though anhydrous, also invariably causes crystallisation.

It would seem from this that anhydrous sodic sulphate, prepared by drying crystals of $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$ at temperatures below 33° C. is not identical with that prepared by heating at temperatures above 33° . They are, probably, isomeric modifications. The former, whether anhydrous (effloresced) or combined with 10 atoms water, always causes the supersaturated solution to crystallise; the latter, whether anhydrous or combined with 7 atoms of water not only never does so, but may be dissolved in a solution already highly supersaturated.

Supersaturated solutions of sodic carbonate and of magnesian sulphate may be prepared without heating in the same manner as those of sodic sulphate. I used for the purpose anhydrous sodic carbonate and partially dehydrated magnesian sulphate.

ON A METHOD OF

FIXING, PHOTOGRAPHING, AND EXHIBITING THE MAGNETIC SPECTRA.*

By ALFRED M. MAYER, Ph.D.

THE figures produced in iron-filings, when these are set in momentary vibration on a surface placed over a magnet have received considerable attention from natural philosophers. The geometrical discussion of these spectra made by Lambert, Roget, and others, have developed their symmetrical properties, and thereby have evolved the law of that action which emanates from the magnet. De Haldat has used them as a means of exploring the distribution and intensity of the effect of juxtaposed magnets variously arranged. But, above all, have the researches of Faraday and W. Thomson on "the magnetic field," and on "the lines of magnetic force" given to these spectra—even when merely regarded as conventional symbols—an importance which has been fully shown; especially by Faraday, who was guided by their consideration to some of his most important discoveries. They have thus risen to so high a theoretical importance that a method which will fix them without danger of distortion, photographically reproduce them, and readily serve to exhibit them to the largest audiences, will, I imagine, be acceptable to both investigators and lecturers.

The only process of fixing these spectra known to me is that practised by De Haldat and Faraday, which, however, is but an application of the magnetic spectra of the method previously invented by Savart for preserving the Chladni figures of vibrating plates. In this process the spectra, produced in the usual manner either on glass or card-board, have pressed upon them a sheet of paper coated with mucilage, to which the filings adhere. In this operation of the transfer many particles are deranged from their positions and the figures are yet more distorted by the shrinkage of the wet paper, and are therefore not fit to

* A more detailed account of the experiments here referred to was published early in 1869 in the *Bulletin de la Société vandoise des Sciences Naturelles*, vol. x., p. 145.

* See a neat "Démonstration par le calcul des courbes magnétiques de la loi de l'inverse du carré de la distance," by M. Cellerier, published as a note on p. 592, vol. I., of *De la Rive's Traité d'Électricité*.

serve in measures of precision; while the impressions cannot be exhibited with much more facility than the originals.

My process is as follows:—a clean plate of thin glass is coated with a firm film of shellac,* by flowing over it a solution of this substance in alcohol,* in the same manner as a photographic plate is coated with collodion. After the plate has remained a day or two in a dry atmosphere, it is placed over the magnet, or magnets, with its ends resting on slips of wood, so that the under surface of the plate just touches the magnet. Fine iron-filings, produced by "draw-filing" Norway iron which has been repeatedly annealed, are now sifted uniformly over the film of lac by means of a fine sieve. The spectrum is then produced on vibrating the plate, by letting fall vertically upon it, at different points, a light piece of copper wire. The plate is now cautiously lifted vertically off the magnet and placed on the end of a cylinder of pasteboard, which serves as a support in bringing it quite close to the under surface of a cast-iron plate (1 foot in diameter, $\frac{1}{4}$ inch thick), which has been heated over a large Bunsen-flame. Thus the shellac is uniformly heated, and the iron-filings, absorbing the radiation, sink into the softened film and are "fixed."

I generally allow the heat to act until the metallic lustre of the filings has disappeared, by sinking into the shellac, and the film appears quite transparent. This degree of action is necessary when photographic prints are to be made from the plate, but when they are to be used as lantern slides I do not carry the heating so far. After the plate has cooled, it is allowed to fall upon its ends, on a table, so that any filings which have not adhered may be removed.

A short experience will give the proper strength of shellac solution to obtain a film so thick as *just to be sufficient to hold the filings*, and the requisite amount of heat to firmly cement them, without injuring the transparency of the film.

The plates can now serve (1) for the most accurate measures upon the magnetic field; (2) for a photographic positive, which, in the printing-frame will produce the lines in white upon a dark ground, giving most beautiful and distinct impressions;† (3) or, if it is required to exhibit these figures to an audience, the plates are provided with glass covers, kept from touching the spectra by intervening slips of cardboard, and there result "slides," in every way fit for giving a fine exhibition, when the images are projected upon a screen. I have thus obtained images, clear and sharp, of over 12 feet in diameter.

By this process many plates have been produced; † showing the action of single magnets of various forms, and of juxtaposed bars; as well as the effects of electric currents led by wires through holes drilled in the plates. Those exhibiting the inductive action of magnets on bars of soft iron and the interaction of magnets and electric currents are peculiarly interesting. An approximate representation of the resultant lines of the terrestrial magnetic action has been obtained by magnetising *equally tempered* steel discs of from 2 to 3 inches and even more in diameter. The magnetic axis or axes of these discs are *predetermined* by making them the continuations of the axes of very powerful electro-magnets, terminated with cones of soft iron with slightly rounded apices. The arcs of the great circles, including the terrestrial magnetic poles, having been calculated, the axes of the electro-magnets are inclined to that angle, while the steel disc is held close to their poles. On passing the current the disc is magnetised and we have an approximate representation of a section of the earth's magnetic effect. These

* The shellac dissolved in strong alcohol is allowed to stand a week or more, and the clear supernatant solution is then decanted.

† Photographic prints from a series of eight of these plates I have presented to Harvard College; American Academy of Sciences; Sheffield Scientific School; Columbia College; Stevens's Institute of Technology, Hoboken; Lehigh University, Pa.; American Philosophical Society; Franklin Institute; Peabody Institute, Balt.; Smithsonian Institution; Chicago Academy of Sciences; and to the University of Virginia.

† Several of these are 16 inches long by 10 wide.

results when viewed as photographic prints, or, as exhibited by the lantern, are so beautiful and instructive as to appear to me to warrant this somewhat formal description of the process of their production.

PS. Since sending the above to press I have subjected plates, coated with "sensitised" collodion to the action of the magnetic field. I had hopes of thus obtaining a *physical* impress on the plate which would appear on flowing the "developer." Sensitised films on glass and on iron plates were placed over and between the poles of an electro-magnet with cores 1·7 inches in diameter. Some plates were developed after removal from the magnet, others while under the magnetic action—with and without the light having acted upon them—but no trace of effect has been detected.

I had also imagined that the magnet's action should have placed the affinities in a more unstable condition, so that the film would rise in sensitiveness after exposure in the magnetic field; but this, also, I could not detect; nevertheless, I have not given up the supposition that some action will be evolved when more appropriate films, far higher magnetic action, and more delicate measures of actinic effect are used.—*American Journal of Science.*

ON THE EFFECT OF CERTAIN METALLIC SUBSTANCES BESIDES IRON ON CARBONIC OXIDE, INCLUDING SILICON.*

By I. LOWTHIAN BELL.

(Concluded from p. 260).

Cobalt.

A COBALT oxide was prepared from the purified nitrate in the same way as the oxides of nickel above described.

It was almost pure Co_3O_4 (Co 73·5, O 26·5), its composition being—

Co 73·3
O 26·7

A small trace of Ni might be present, but if so, it could not materially affect the result, inasmuch as CoO is much more powerful in splitting up CO than is NiO.

Specimens of this oxide of cobalt (Co_3O_4), were exposed in the lead-bath arrangement.

	Expt. 399.		Expt. 400.	
	Time of exposure—	7½ hours.	10 hours.	
	Temperature—	Zn fused, Sb not.	Zn fused, Sb not.	
Composition of product.	{ Co soluble in I	47·2	{ 17·3	
	{ Co insoluble in I		{ 20·4	
	{ Carbon	46·4	{ 56·8	
	{ Oxygen	6·4	{ 5·5	
		100·0	100·0	

The condition in which the cobalt exists was not determined—that is, whether part as metal and part as oxide, or whether the whole was as suboxide. In Experiment 399, the oxygen per 100 of total cobalt present was 13·56, and in Experiment 400 14·58, which correspond nearly with Co_2O (100 Co, 13·6 O). It was ascertained that the anhydrous Co_3O_4 used was attacked by iodine and water, so that it was not possible by the use of this reagent, as in the case of iron and nickel, to distinguish between metallic cobalt and its oxide. The oxygen in Experiment 400 existed to the extent of 27·0 per 100 parts of that cobalt which was found to be insoluble in iodine and cold water, which indicates that the action of iodine on the Co_2O probably formed gives rise to CoO, and not Co_2O_3 ; the former formula requiring 27·1 of O per 100 of Co, thus:—

* From the "Chemical Phenomena of Iron Smelting."

which indicates a double difference between the behaviour of the lower oxides of Co and Fe under these circumstances. The fact that the Co_2O_3 originally used was attacked by iodine, however, probably indicates that Co_2O_3 is producible by the action of iodine on the lower oxides; a reaction probable, *a priori*, from the well-known formation of Co_2O_3 from the action of chlorine on alkalis solutions of cobalt.

The presence of CO_2 to the extent of an equal volume does not prevent CO from completely reducing the cobalt oxide under examination (Co_2O_3).

Expt. 401.

To ascertain the power of the spongy metallic cobalt to withdraw O from CO_2 , in—

Expt. 405.—120 c.c. of gas unabsorbed by KOH was collected by passing CO_2 over Co at a bright red heat for thirty-five minutes. The 120 c.c. so obtained contained 96 per cent of CO.

Platinum—

Although there was little probability of a metal having so feeble an affinity for oxygen as platinum to exert any power of splitting up CO, the following experiments were performed, under the idea that possibly the dissociation of CO by heat alone (which Experiment 373 *et seq.* show, does not readily take place), might be assisted by the occlusion of that gas in the pores of a spongy substance gifted with high absorbing powers for gases.

This metal was obtained in its spongy condition—

(A) by ignition of ammonium chloroplatinate.

(B) „ potassium chloroplatinate and washing product.

Expt. 406.—Spongy platinum (A), inert, at melting zinc.

Expt. 407.— „ „ „ „ low red heat.

Expt. 408.— „ „ (B), „ melting zinc.

Expt. 409.— „ „ „ „ low red heat.

In one of these cases there was a trace of carbonaceous matter deposited, due, probably, to the presence of hydrocyanic acid vapour in the CO employed, as the gas used was not wholly freed from this impurity.

Silicon—

Expt. 410.—A specimen of this element, in its graphitoid form, weighing 1·405 grms., dried at 100° C. (212° F.), lost 0·005

Just ignited, and lamp removed, lost 0·013

Then heated to redness for half an hour, it gained 0·018

Ditto, half an hour more, it gained 0·006

Ditto, half an hour more, it gained 0·004

Na_2SO_4 to 100 0·010

It contained some body, probably

* A more detailed account of air at a red heat removed, and published early in 1869 in *Théon*, oxidisable at this temperature. *Sciences Naturelles*, vol. x., p. 1

The 1·397 grms. of silicon remaining after this treatment were exposed to a stream of pure CO for six and a half hours, at a temperature a little above that of melting zinc:—

No change in weight.

Expt. 411.—The same specimen was then exposed to CO at a bright red for a period of six hours, precautions, before and after the experiment, in both cases, being observed to exclude atmospheric air:—

	Per cent
The gain in weight was	0·18
Burnt in oxygen, gain on original substance was	0·29
CO_2 collected = 0·08 grm., equal to C	0·15

Looking at the previous behaviour of this specimen of graphitoid silicon, it is doubtful whether this small quantity of C is owing to carbon deposition, but may rather be due to trace of C or graphite in the silicon itself.

Titanic Acid—

Expt. 412.—Cubical crystals of nitride of titanium are commonly found in the hearths of extinguished blast-furnaces. The specimen of amorphous TiO_2 employed was obtained by igniting ammonium titanate: 0·464 grm. was exposed for six and a half hours to a temperature a little above that of melting zinc. The TiO_2 was faintly blackened on its surface:—

	Per cent.
The gain in weight was	1·2
Burnt in oxygen, it lost again	1·0
CO_2 collected 0·019 = C on original TiO_2	1·1

Expt. 413.—The specimen of TiO_2 , freed from carbon by ignition in O, would consist of—

	Grm.
Ti	0·283
O	0·181
	0·464

It was exposed to a bright red heat for six hours to a stream of pure CO. It was ascertained, by combustion in oxygen, collection of CO_2 , and difference of weight, to be now composed of—

Ti	0·2830
C	0·0040
O	0·1725
	0·4595

From these numbers, it appears that the TiO_2 has lost 4·7 per cent of its oxygen, and deposited carbon to the extent of 0·9 per cent of the TiO_2 used, or 1·19 per cent of the metallic Ti present.

ON THE
METHODS OF ANALYSIS
AND THE
COMPOSITION OF VARIOUS CHEMICAL
MANUFACTURING PRODUCTS.

By M. GASTON TISSANDIER.

PALM OIL.

PALM OIL is prepared from the fruit of the palm tree (*Clavis Guineensis*) as follows:—On its arrival at maturity, the fruit is plucked and thrown into a heap on the ground, where it is left for about a month. Fermentation is thus produced. When this is sufficiently advanced, the mass is thrown into large iron vats and boiled with water, the fruits being crushed in the hands of the labourers from time to time. After prolonged boiling, they are pounded in rude mortars formed from the trunks of trees, the kernels are removed, and the shells again boiled. The oil then floats on the surface of the liquid, and is collected with large wooden spoons.

Properties.—Palm oil is solid at the ordinary temperature of our climates, its colour is a reddish yellow, and it is esteemed in proportion to the deepness of its colour. Its perfume resembles that of the iris or the violet. It melts at from 30° to 35° C., according to its age, but when freshly prepared its melting-point is lower. It is easily soluble in alcohol, and still more so in sulphide of carbon and ether. About 80,000 tons are annually manufactured. The oil mixes readily with water, which is frequently used to adulterate it: 50 per cent may be added without fear of detection by the most practised eye. In order to estimate the water contained in palm oil, a certain weight of it must be heated on a stove at 110° C.; desiccation will then ensue in a few hours. Unadulterated commercial palm oil contains from 3 to 8 per cent of moisture. A very superior quality of oil is obtained from the kernels of the palm, which are very large.

Ash.—Sand or earth is frequently mixed with palm oil during manufacture; to estimate this, calcine 50 grms. of oil in a porcelain capsule, and after the charcoal thus formed is burnt off, weigh the ash obtained. Palm oil sometimes contains from 4 to 5 per cent of sand.

Impurities.—Sundry organic substances, such as the remains of palm leaves, &c., also occur; in order to estimate these, melt 100 grms. of oil in a capsule upon a water-bath, let it stand an hour, decant the limpid oil, and treat the precipitated impurities with sulphide of carbon, so as to dissolve the oil which adheres to the sides of the vessel. The impurities must be thrown on a filter, washed with sulphide of carbon, dried at 100°, and weighed. Some analyses are subjoined:—

Loss in Palm Oil.

	I.	II.
Moisture	8·25	3·12
Ash	0·45	1·20
Organic impurities..	1·01	0·80
Total loss	9·71	5·12

WHITE-LEAD—ZINC-WHITE.

Commercial white-lead is frequently adulterated with sulphate of baryta, carbonate of baryta, and carbonate of lime. The presence of sulphate of baryta may be tolerated when its proportion does not exceed 5 per cent.

The mode of analysis is as follows:—Weigh 1 grm. of white-lead, and calcine it in a small porcelain capsule; treat the residue, while hot, with pure nitric acid diluted with water—this dissolves the oxide of lead, while the sulphate of baryta remains insoluble.

Now filter, and precipitate the filtered liquid with sulphuretted hydrogen; a formation of sulphide of lead will then ensue, and this must be dried at 100° C. and weighed. The liquid, separated from the sulphide of lead, is treated with ammonia and sulphhydrate of ammonia, which will betray the presence of oxide of zinc, which sometimes occurs in white-lead, by precipitating it as sulphide of zinc. Filter this latter, and evaporate the filtered liquid to dryness, previously adding chlorhydric acid; take up the residue with water and chlorhydric acid, and add ammonia and oxalate of ammonia, which will precipitate the lime as insoluble oxalate of lime.

The sulphide of lead is converted, by calculation, into carbonate; the sulphide of zinc is dissolved in chlorhydric acid after calcination, and precipitated as carbonate of zinc by the addition of carbonate of soda. The carbonate of zinc is collected on a filter, washed with boiling water, dried, calcined, and weighed; the calcination transforms it into oxide of zinc, which is thus extracted directly from the specimen of colour under examination.

To ascertain whether the white substance which was insoluble in the acid liquid used in the first experiment be really sulphate of baryta, proceed as follows:—Mix it thoroughly with dry, pure, finely-powdered carbonate of soda; heat it to redness in a platinum crucible, until the fluid mass no longer effervesces; let it cool, and boil it with warm water, which dissolves the sulphate of soda

formed, without acting upon the carbonate of baryta which is formed during the reaction. The aqueous solution should be precipitated by chloride of barium, which determines the formation of insoluble sulphate of baryta; the insoluble substance remaining on the filter is treated with pure chlorhydric acid diluted with water, and should yield a precipitate of sulphate of baryta on the addition of a drop of sulphuric acid.

Occasionally, but rarely, kaolin and clay are met with in white-lead.

The white-lead to be tested is not invariably met with in powder; the specimen may be mixed with oil and turpentine; sometimes its adulteration is not suspected till after its application to walls or wainscoting. In the first case, in calcining the well-mixed paint, take no notice of any oil that may be burnt. In the second, scrape the paint off the wall, and treat it in the same way; care must be taken not to scrape the stone also; it is better to pay attention to the sulphate of baryta only, neglecting any carbonate of lime which may result from the calcareous wall.

Composition of Adulterated White-Lead.

Substances estimated.	I.	II.
Carbonate of lead	85·25	44·33
Oxide of zinc	—	5·30
Sulphate of baryta	10·12	40·25
Carbonate of lime	4·63	10·12
Clay	—	—
	100·00	100·00

Specimen No. II. is by no means the most adulterated with which we have met. Some months ago, a so-called white-lead was analysed by us which contained no trace of lead; it consisted of carbonate of lime and sulphate of baryta, the oil and turpentine being replaced by soap-suds.

Zinc-white is subject to the same adulterations as white-lead, and the analytical process for oxide of zinc is the same as for white-lead.

WATER USED FOR FEEDING BOILERS.

All who have the management of steam-engines must have been inconvenienced by their boilers becoming incrustated with deposits, or corroded by nitrous vapours or chlorhydric acid, arising from impurities in the water employed. Water of good quality, such as river water, spring water, and that of streams, seldom contains in solution more than from 1 to 3 decigrms. per litre of saline matter; this generally consists of carbonate of lime, alkaline chlorides, sulphate of lime, and a small quantity of organic matter.

When water contains much carbonate of lime, say 5 to 10 decigrms., it will encrust the boiler, forming a hard and injurious deposit; this is a *calcareous* water. If it contains much sulphate of lime, say 1 grm., it will leave an abundant deposit, and will not cook vegetables or dissolve soap; this is a *selenitic* water. Lastly, if it contains nitrate of magnesia or chloride of magnesia, it produces nitrous vapours and chlorhydric acid, which corrode the metal; this is a *corrosive* water.

To ascertain whether the above-mentioned substances are contained in a water, pour 1 litre of it into a very clean, deep dish, and evaporate it to dryness over the water-bath at 100° C. The residue must be carefully scraped off the dish with a platinum spatula, swept together with a brush, and weighed; its weight will give some notion of the quality of the water, which is pure in proportion to the smallness of the deposit.

Nitrate of Magnesia and Chloride of Magnesium.—The dry residue is weighed, and extracted with alcohol at 40°; this dissolves only the chloride and nitrate of magnesia and a small quantity of alkaline chlorides. Filter, wash with alcohol, and evaporate the alcoholic solution to dryness over the water-bath on a platinum capsule.

Heat the residue gradually at a higher temperature; if red nitrous vapours appear, it contains nitrate of mag-

nesia; if the vapours are white and acid, and form a thick white cloud upon contact with a glass rod moistened with ammonia, they consist of chlorhydric acid. In both these cases, the water is corrosive, and on its evaporation will attack metals. After completing the calcination, filtering off the resulting magnesia, and carefully weighing it, it may be changed by calculation into nitrate of magnesia or chloride of magnesium.

This method is far preferable to the direct estimation of the magnesia in water; for water may be magnesian without being corrosive, as all salts of magnesia do not thus yield acids when subjected to heat. Here the acids are plainly perceived, and the corrosive action is proved.

Chlorine.—Measure 1 litre of the water to be tested, and precipitate the chlorine by a slight excess of nitrate of silver, collect the chloride of silver on a filter, and wash it with boiling water. After drying on a stove, fuse partially in a small tared porcelain capsule, weigh it, and calculate the quantity of chlorine contained.

Sulphuric Acid.—Precipitate 1 litre of water by chloride of barium. The sulphuric acid is precipitated as sulphate of baryta.

Lime.—Precipitate 1 litre of water with oxalate of ammonia, and all the lime will be precipitated as oxalate of lime.

The sulphuric acid is transformed into sulphate of lime, and the excess of lime calculated as carbonate of lime.

The estimation of these substances may be directly verified by working upon the dry residue which was exhausted by the alcohol. That portion which is insoluble in alcohol is treated with water, which dissolves the chlorides and alkaline sulphates, and leaves the carbonates of lime and magnesia, sulphate of lime, and silica in an insoluble state.

That part of the residue which is insoluble in water must be treated with acetic acid, which dissolves only the carbonate of lime, and does not attack the sulphate. Evaporate the acetic solution to dryness, calcine the residue, and all the carbonate of lime contained will be reproduced. By evaporating the aqueous solution, the alkaline chlorides and sulphates are obtained; it is, therefore, obvious that by a succession of solvents it is possible to separate all the contained salts, and in some measure to isolate them.

It need scarcely be said that these methods are only intended to be practically and expeditiously applied by operators, and that no attempt at a mode of completely analysing water is here contemplated.

Some estimate of the purity of water may be gained by simply examining the precipitates yielded with nitrate of silver, chloride of barium, and oxalate of ammonia. Pour these three reagents successively into a water of good quality, and the cloudiness will be slight; repeat the process with *selenitic* well-water, and abundant white precipitates will ensue, due to the action of the chloride of barium and oxalate of ammonia.

Hydrotimetry.—This method, which has been much over-rated, is far inferior to that above described. It is based upon the action of water upon a standard alcoholic solution of soap. This solution is poured into the water, drop by drop, by means of a burette, and well shaken at each addition, ceasing when a persistent froth is formed; the number of divisions of the burette gives the hydrotimetric standard. Unfortunately, when water is very much charged with sulphate of lime, it immediately yields a persistent froth; and I am now in possession of well-water which, containing 1·20 grs. of sulphate, should estimate more than 100°, whereas the soapy froth is persistent at 8°. The latter figure indicates that the water is excellent, while it is really execrable.

Purification.—When water contains much bicarbonate of lime, it may be freed from a portion of it by adding milk of lime, which will precipitate insoluble carbonate of lime. If the water to be purified be placed in large reservoirs, and agitated while the milk of lime is poured in, it will be found, when it has settled, to contain much less

bicarbonate of lime. The action of lime also removes the corrosive properties of water; the lime, in fact, changing chloride of magnesium into chloride of calcium, which does not decompose under the influence of heat, and transforming nitrate of magnesia into nitrate of lime, which decomposes only at a very high temperature, and may be evaporated without evolving nitrous vapours. These reactions are, however, difficult to bring into practice, and unsuited to the purposes of manufacture.

MANUFACTURE OF SODA AND CARBONATE OF SODA FROM CRYOLITE.*

By J. LAWRENCE SMITH.

MANY and vain have been the attempts to supersede the process of Leblanc for the production of soda, and vast amounts of ingenuity and capital have been expended without success. But this statement does not apply to the production of soda, to a limited degree, out of a curious mineral found in Greenland called cryolite. This mineral was exhibited in abundance at the Exposition, and as there is an important manufacture of soda from it established at Natrona, Pennsylvania, the details of the method employed will be briefly described. These details have been kindly furnished to me by J. A. Hagemann, the chemist of the Danish Cryolite Mining Company, who directs at this time the manufacture of soda from cryolite by the Pennsylvania Salt Manufacturing Company. We may look for the best information on the subject of the above-named company's works, which are imitations on a large scale of the factory built by Julius Thomsen, of Copenhagen, in 1856. Some information has also been obtained from an essay by Samuel F. Simes.

Cryolite and its Source.

Before proceeding to a description of the process of manufacture, it is well to give some short account of this mineral and its present commercial movement.

The mineral cryolite, or "ice stone," has been known as a mineralogical rarity for many years, as far back as the latter part of the last century; thirty years ago it was worth fully a dollar an ounce, and it was considered only as a rare and curious mineral, of no value in the arts. Up to 1850 no attempt had been made to put it to any practical use, although it was known to exist in Greenland in large quantities and to contain a large amount of soda, for its composition is—

3 Sodium	69·00
2 Aluminium	27·26
6 Fluorine	114·00
	210·26

It has a specific gravity of 2·95, with a hardness of 2·05. Much of it is found colourless and pure. The associated minerals are galena, blende, spathic iron ore, iron pyrites, and copper pyrites.

With the exception of some few scattered specimens that occur at Miask, in the Ural mountains, it is found exclusively in immense quantity. It is procured from the mines of Ivigtout on the west shore of South Greenland, on Arsuk Fiord, between Julian's Hope and Frederick's, latitude 61° north, longitude 48° west. The main deposit here forms a mass of 600 feet in length, and 200 feet in width, and descending to an unknown depth. It lies at the base of granite hills, that rise a little distance from the edge of the Fiord, the shores of which are very bold and are almost fathomless a few feet from the shore.

The Danish Government is the owner of this mine, and in 1864 Christian IX. granted the exclusive right of mining

* From the Report of the United States Commissioner to the Paris Exposition.

cryolite to the "Cryolite Mining Company of Handelshelhabet," a company organised in Copenhagen. This contract was made by a Danish company, in consequence of the results of the labours of a young Danish chemist, Julius Thomsen, in 1850, who discovered a cheap and easy method of rendering cryolite available in technical chemistry for the manufacture of soda and alum, and his process is carried on in Europe and this country on such a scale as to consume annually 12,000 to 15,000 tons of cryolite.

Process of Decomposing Cryolite.

Thomsen's process of decomposing cryolite is simply by lime, either the wet or dry way. The decomposition may be represented by the following formula:—

Another method is to calcine finely-powdered cryolite and mix it with six equivalents of lime; the product will be "caustic soda, aluminate of soda, and fluoride of calcium." Another is to boil cryolite with the same proportion of lime in the form of milk of lime, and a similar decomposition takes place. The soda and aluminate are soluble in water; the latter is subsequently decomposed by carbonic acid. Both the wet and dry process will now be described.

The Dry Process.—The cryolite is dried in a furnace, and by a crusher is reduced to small fragments, which are ground in a burrstone mill to a fine powder, and uniformity in the powder is insured by passing it through a bolter of fine wire gauze. The powder is then mixed with slaked lime, or with pulverised chalk, in proportion to its purity, so that for each equivalent of pure cryolite there shall be a little more than six equivalents of lime. This mixture is effected on chaser mills, such as are used for crushing linseed and other oily grains. This mixture is now calcined, and here arises the great difficulty of the process, for the soda or carbonate of soda and fluoride of calcium fuse at a low temperature, and if allowed to fuse would almost entirely prevent the subsequent lixiviation with water. Care must therefore be taken to prevent the temperature from rising high enough to fuse the mass, while at the same time the mass must be heated sufficiently to effect the decomposition.

When the factory at Copenhagen was erected in 1856, this decomposition was effected in iron retorts similar to gas retorts, and set in the same way, and the carbonic acid so liberated (when chalk was used) was conducted to the vats to decompose the aluminate of soda from a previous operation. But this process entailed costly repairs, and much expensive handling. Thomsen then constructed a furnace, which is now successfully used in all the cryolite factories.

It contains two fire-places at opposite ends. The flame from one of them passes underneath the hearth, which is formed of large slabs of fire-clay 2 feet square, and supported on square pillars. At this farther end, the flame meets the other, and both pass over the hearth, then rise and pass over the arch, and under an evaporating pan, to which they give off the last portions of heat. Finally, they pass into the flue of the chimney.

The mixture is spread on the hearth about 3 inches thick, and is not disturbed for about one hour, at which time it is turned over with a rake, and again left for about three-quarters of an hour, after which it is drawn out, and fresh material is introduced, each charge being about 1000 pounds. The decomposition should be complete in the portion withdrawn, and it forms a granular, loose mass of an ash colour. After the mass has thoroughly cooled, it is lixiviated in an ordinary tank, and the dissolved soda and aluminate of soda is drawn off, and the residue is properly washed. The solution will, on an average, mark 26° to 28° Baumé.

The lye, being a strong solution of soda, carbonate of soda, and aluminate of soda, is treated with carbonic acid, in order to produce carbonate of soda and alumina. The

carbonic acid is produced by the combustion of coke, and the products of combustion are drawn off by means of a fan, and passed through stacks filled with coke, down which water is made to trickle; and in this way the carbonic acid is washed and purified. The purified gas is passed from these stacks into a large horizontal cylinder, from 40 to 50 feet long, through the middle of which a shaft with paddles rotates. The cylinder is about half filled with liquor, the paddles are put in motion, and the gas is let on through one end of the cylinder, the unabsorbed gases escaping at the other end. When the solution is saturated with carbonic acid, it is run off into settling-boxes capable of holding one charge. In about from four to six hours the alumina will have separated from the liquor which is drawn off, and the deposited alumina is freed from the adhering soda by washing it with water, and filtering upon proper filters. The clear solutions first drawn off has a density of about 31° Baumé, and the alumina is left in the form of a granular powder. In this way two valuable products are produced from the cryolite—carbonate of soda and alumina. The latter contains but a trace of soda, and is a valuable material for the manufacture of alum and sulphate of alumina.

Considering the nature of the mineral and its impurities, sometimes amounting to 10 or 15 per cent, the carbonate of soda is remarkably pure, its only impurity being one or two per cent of sulphate of soda, the sulphuric acid having been formed from the sulphides that are associated with the cryolite.

The Wet Process.—If cryolite be boiled with six equivalents of lime, the decomposition which takes place is similar to what occurs in the dry process; but if two equivalents of cryolite be boiled with fifteen equivalents of lime, the resulting product will be caustic soda, aluminate of lime, and fluoride of calcium.

In either case the decomposition is effected as follows:—Into a large vertical cylinder, provided with a perpendicular shaft having paddles, and a steam-pipe, ending close to the bottom in a perforated ring, is introduced milk of lime, made from about 15,000 pounds of good lime. The paddles are now put in motion, and the mass is agitated for a little time, and the liquid is then assayed and measured, so as to ascertain the exact amount of lime present. The cryolite is then added in fine powder in the proportion desired to accomplish a given result. Two equivalents of cryolite, and twelve equivalents of lime will produce, as already stated, caustic soda and aluminate of soda. Fifteen equivalents of lime will furnish all the soda as caustic soda, with aluminate of lime. Fluoride of calcium is formed in both cases.

After two or three hours' boiling and agitation, the decomposition is generally completed (testing will indicate the liberation of all the soda), and the contents of the agitator are discharged on a suitable filter. The clean liquor which will form on top of the sediment is drawn off, and the sediment is treated with water as long as the filtered liquid contains soda.

If the first proportion of lime has been used, and aluminate of soda has been formed, the liquid is treated with carbonic acid, as in the dry process, and all the soda is converted into carbonate, and the alumina is deposited as an insoluble residue. If the latter proportion of lime is used, and all the soda be in the solution as caustic soda, all that it is necessary to do is to evaporate the liquid to dryness in pans or kettles. In this manner caustic soda, containing 75 per cent of NaO is manufactured on a very large scale at Natrona.

It is evident that the wet process is decidedly the simpler of the two, there being less handling, and less costly apparatus; but the feeble strength of the lye produced (10° B.) by this process, and consequently the large amount of water to be evaporated, is a great drawback to it. Where alumina is of but little value, and caustic soda is much sought after, the wet process with fifteen equivalents of

lime may be most profitably employed. Where the contrary is the case, the dry process is to be preferred, producing a lye of 26° to 28° B., and requiring but little concentration in order to crystallise.

Besides working out all the details of this process, Julius Thomsen has devised volumetric processes of analysis adapted to different stages of the operation. Weber and Brother, of Copenhagen, not only furnished all the means necessary for conducting his experiments, but established a factory in Copenhagen, and sent vessels to Greenland for the cryolite. Their factory has been the model on which others have been erected.

There are four establishments in Germany, consuming annually about 2000 tons of cryolite; and in 1867 the one in this country was erected by the Pennsylvania Salt Manufacturing Company, having a capacity for working up about 6000 tons of cryolite. This company, in 1867, imported 8000 tons, and sent out to Greenland during the summer nineteen vessels of an average capacity of 450 tons, of which two were lost in the ice. The approach to the coast is considered dangerous on account of the fields of ice, which sometimes form a thick and impenetrable belt of 80 to 100 miles in width. Off the western coast of Greenland the wind scatters the ice, and a good navigator can penetrate the openings without delay. No loss of life has yet occurred in this trade, as the ice affords a refuge for a shipwrecked crew until removed by the Esquimaux, or until they escape by their boats to the settlements. The mines are worked, from May to October, by about one hundred and fifty men. In the salt works of Natrona, Pennsylvania, more than half a million of dollars have been invested, and employment has been given to five hundred men. The alumina manufactured there in connection with the soda is supplied to the largest makers of alum in this country. The various manufactures from cryolite have a market value of over 1,500,000 dollars in gold.

There has been no important improvement on Thomsen's processes, except it be one by G. A. Hagemann, on which a patent has just been obtained.

Bauxite (a mineral containing 80 per cent of alumina) is sometimes mixed with the cryolite to increase the yield of alumina.

Much space has here been devoted to this manufacture of cryolite soda, from the fact that cryolite and its products were conspicuous in the Exposition, and that the value of cryolite and its treatment, as a soda-yielding substance, is but little understood and appreciated by technical chemists generally.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

June 1st, 1871:

Professor FRANKLAND, F.R.S., President, in the Chair.

The following gentlemen were elected Fellows:—H. Adrien, H. Durham, G. Martineau, E. Neison.

Dr. DEBUS, F.R.S., delivered a lecture on "Ozone."

The lecturer began by stating why ozone is considered to be an allotropic modification of oxygen; then discussing whether there are reasons to assume the existence of two allotropic modifications, and concluded with a review of some of the properties of ozone.

Van Marum, in 1785, seems to have been the first to observe that the passage of electric sparks through oxygen causes this gas to become more energetic in its action on other bodies, and to assume at the same time a peculiar odour. Next Schönbein, in 1840, took this subject up, and instituted a series of experiments on the nature and properties of ozone. He proved that the gas developed at

the positive electrode, when a galvanic current is passed through water acidulated with sulphuric acid, possesses the same properties as oxygen which has been subjected to repeated electric discharges, and that the electrolytic oxygen retains those properties when kept over water. He attributed the change undergone by the gas to a peculiar substance to which he gave the name of ozone. It was further found by him that ozone is formed in air, when phosphorus is allowed to oxidise in it. His experiments, however, led to no positive results as regards the nature of ozone; his theory that water and air contained a small quantity of an unknown substance, which in composition was analogous to hydrochloric acid, and which by electricity and other means was decomposed into hydrogen and ozone, was an opinion that could not be supported by facts.

The first experiments establishing the fact that ozone was only an allotropic modification of oxygen were made by Marignac and De la Rive about 1845. Among the more important observations Marignac had made regarding ozone were: That it is best obtained by passing air slowly over phosphorus in a tube 1 metre in length and 6 m.m. in diameter; that it cannot be obtained from dry air, neither from dry and pure oxygen by means of phosphorus; and that ozone contains nothing but oxygen. Schönbein did not accept this conclusion, but asserted (1847) that ozone was a peroxide of hydrogen. His opinion was supported by the experiments of Williamson and Baumert. It appeared, therefore, that there existed two kinds of ozone: the one, obtained by passing electric sparks through oxygen, or by the action of phosphorus on air, being allotropic oxygen; and the other, obtained by the agency of the electric current, being a peroxide of hydrogen.

Against this latter view Andrews maintained that ozone prepared by electrolysis did not differ in its nature from ozone obtained through other methods. He was borne out by Soret, who, in 1863, made some experiments which in many respects were only a repetition of those instituted eighteen years earlier. For drying the gas to be examined, Williamson employed an ordinary chloride of calcium tube. It was not known in 1845 that the last traces of moisture cannot be removed from a gas unless the chloride of calcium tubes are very long.

Thus, according to our present knowledge, ozone is an allotropic modification of oxygen.

The lecturer next proceeded with the consideration whether there was another modification of oxygen, the so-called antozone. This substance is said to be formed either by the action of concentrated sulphuric acid on baric peroxide, or along with ozone when oxygen is submitted to silent electrical discharges, and one of its best characteristics is the property to assume in contact with water a cloudy appearance and to oxidise the water to hydrogen peroxide. But an experiment of Messrs. Nasse and Engler shows that antozone is only peroxide of hydrogen vapour diffused through a very large quantity of air or oxygen.

There exists, therefore, only one allotropic modification of oxygen, viz., ozone.

About the properties of ozone, the lecturer did not think it necessary to say much, as they are so well known, and he directed attention only to one reaction—the decomposition of potassic iodide. This reaction is differently explained by different observers. Schönbein's observation, however (according to which iodine is protected through potassic iodide against the action of potassic hydrate), seems to lead to the best explanation. It may be assumed that on adding potassic hydrate to a solution of iodine these reactions take place:— $\text{KHO} \times \text{I}_2 = \text{KIO} + \text{HI}$, and then $\text{KH} + \text{OHI} = \text{KI} + \text{H}_2\text{O}$. Now, if an excess of potassic iodide be added, the potassic hypo-iodite and the potassic iodide produce again iodine and potassic hydrate, thus:— $\text{KI} + \text{OKI} = \text{KKO} + \text{I}_2$, then $\text{KKO} + \text{H}_2\text{O} = 2\text{KHO}$, and here the excess of potassic iodide will prevent the potash from attacking the iodide, but allow the latter to act upon starch. From this, now, the action of ozone on a mixture of potassic iodide and starch is easily understood: In the

first place, the potassic iodide being in excess, ozone forms in presence of water potassic hydrate and free iodine. But as by degrees the potassic iodide is decomposed and diminished in quantity, the potash commences to act on the iodine and to form potassic iodate and iodide. The latter is acted upon by the ozone until a certain amount of KHO has accumulated and can with free iodine form iodate and iodide. This process goes on until all the iodide is converted into iodate and the mixture has lost its blue colour.

NOTICES OF BOOKS.

Analytical Tables for Students of Practical Chemistry.
By J. CAMPBELL BROWN, D.Sc., Professor of Chemistry and Toxicology at the Liverpool Royal Infirmary School of Medicine, and Lecturer of the Liverpool School of Science. London: J. and A. Churchill. Liverpool: A. Holden. 1871.

THE author has published this work, the first part of a series: at the request of several teachers as well as students. The tables are not intended to supersede *viva voce* instruction, but to be used as notes by which to follow and recall to mind the demonstrations of the teacher. The following are the contents of this useful book:—Table for the Analysis of Gases; Preliminary Examination for Simple Salts and Mixtures; Table for the Separation of Metals into Groups; followed by six tables for the Detection of the Separate Groups; General Examination for Mineral Acids; Special Tests for Mineral Acids; Examination of Organic Compounds; Behaviour of Some Neutral Substances whose Presence may be Suspected by their Taste; Table for the Separation of Organic Bases; Characteristic Tests for the Principal Organic Bases. Although these tables are arranged for the examination of complex substances, it is evident that they may be conveniently employed for the detection of simple substances by omitting all those details which refer to the separation of one substance from another.

CORRESPONDENCE.

AGRICULTURE AND CHEMISTRY.

To the Editor of the Chemical News.

SIR,—Permit me to say a few words on two matters of great agricultural importance which have been recently alluded to in the CHEMICAL NEWS. I refer to the scientific education of farmers' sons and to the manure trade.

In the year 1866 I made an experimental trial of the plan lately proposed by Mr. Marshall Hall. I then commenced a series of forty lectures to a class of farmers' sons at Kingscote, a village about 15 miles from the Agricultural College. The lectures were given under the auspices of the well-known Kingscote Agricultural Association, a thriving and enlightened farmers' club. The class, numbering something like twenty, was quiet, regular in attendance, and passed a fair examination at the close of the course, which extended over two years. The lectures were devoted to inorganic, organic, and agricultural chemistry, the subjects being taken in this order, that a good scientific basis for the agricultural application of chemistry might be secured. At the same time an agricultural bias was given, even to the earlier lectures, by illustrative experiments, made, as far as possible, with substances produced on the farm or useful to the farmer, with plants, soils, and manures. More than this, the pupils of my class were encouraged to repeat the chief experiment shown in the lectures, and several of them actually fitted up little laboratories of their own at home. I regret that I have not been able to repeat so encouraging an

experiment, but the great difficulty was in the distances which both students and teacher had to travel in order to reach the place of meeting. My own journeys, during this course, give a total length of 1200 miles, and, owing to the absence of a railway, had to be performed under peculiar difficulties. But I am convinced that the system which I carried out in 1866-7, and which Mr. Marshall Hall has just suggested in his letter to the *Devizes Gazette*, may, when suitably modified in accordance with local circumstances, be carried out with immense advantage to the general farming interest. I ought to add that the scheme above described owed much to the suggestion and help of the Principal of the Agricultural College. I hope, on another occasion, to develop further, a method of scientific instruction for young farmers, and to describe a plan for the creation in England of agricultural experimental stations where chemistry might be brought to bear upon agriculture in several directions.

I would now ask for a little more space, in order to describe briefly one of the most obvious aspects of the manure question. How is it that manufactured manures, such as the different varieties of superphosphate of lime, are often sold to farmers at a price so much higher than that at which their crude constituents can be purchased? We know that the process of manufacture is not tedious or troublesome, and that its cost is small. And we know also that many manufacturers of superphosphate supply manure-dealers wholesale with fair qualities of this manure on terms which allow the latter a broad margin of profit, but that the farmer has to pay not the manufacturer's charges only, but those of the dealer as well. Mr. Little has pointed out* one of the ways in which a farmer may get a manure for, say, £4 per ton, which shall be guaranteed to contain 26 per cent of "soluble phosphate," and for which he would have to pay, in the ordinary course, from 5 to 6 guineas, if not more. But it is only fair to point out that two manures may analyse equally well and yet differ in their effectiveness very considerably. This remark applies with especial force to nitrogenous manures in which the nitrogen may exist in various degrees of availability. It is, on the other hand, highly probable that the soluble part of a mineral superphosphate, provided some decomposing carbonaceous matter be present, is as useful as the corresponding constituent of a bone superphosphate. Thus the argument for difference of price which manufacturers urge by reason of their employment of the best materials must not be pushed too far. An instance in point may serve to illustrate my meaning clearly.

In the spring of this year some samples of manure were sent to me for examination. I was subsequently informed that the price charged for them was £8 8s. per ton. Now, on analysis, I could only rate them at about £5 5s. per ton, assuming their several manurial elements to have been derived from the most valuable crude materials. But what was the argument against my valuation which Messrs. A and Co., the well-known manufacturers of this manure, urged with the farmer who had purchased the manure? It was to the following effect:—"Our manures are the final result of long-continued thought and experiment; they have been successfully submitted in the field to the severest trials by numerous farmers; we have sunk thousands of pounds in arriving at our present processes of manufacture, &c., and, moreover, our manures are compounded and mixed in such admirable proportions, and with such exquisite skill, that they must not be judged of by the inadequate test of chemical analysis." Let us pursue this admirable argument a step farther: let us apply it to an animal's food instead of a plant's food. Only mix stones with bread, with a sufficient amount of exquisite skill, and anxious thought, and long experience, and the innutritious stone or other rubbish becomes a most useful material for sustaining life!

Unfortunately, the farmer has not only to deal with mixed manures (which too often justly deserve the epithet "nostrum" which Mr. Little uses in this connection), but

* CHEMICAL NEWS, vol. xxiii., p. 248.

he has to suffer from the gross frauds of purposed adulterations. We shall not easily forget the revelations as to the ochre-grinding machine at a Liverpool guano-works, nor the *exposés* which are continually made in our agricultural journals. But most manures are tempting subjects for adulteration. After all they won't crystallise and won't distil, and so come under the great class of "dirts." Here is an analysis of a very dirty dirt indeed, which was analysed in my laboratory last week, having been purchased for a good superphosphate, at a good price, by a deluded agriculturist.

Analysis of Superphosphate; from Mr. —, May 24, 1871.

Water	17.33	per cent.
*Organic matter and combined water	16.31	"
†Monocalcic phosphate	1.74	"
Tricalcic phosphate	5.02	"
Calcium sulphate	12.92	"
Common salt	16.82	"
Sand	19.00	"
Alumina, ferric oxide, and } alkaline salts. }	10.86	"
	100.00	

It is evident than in making this exquisite mixture the zeal of the operator had outrun his discretion: he had, evidently, scraped the floor a trifle too hard.—I am, &c.,

A. H. CHURCH.

Royal Agricultural College, Cirencester.

MISCELLANEOUS.

Marlborough College.—The Head Master of Marlborough College having determined to introduce natural science as part of the school work, Mr. G. Farrer Rodwell has just been elected science master, and therefore resigns his present appointment at Clifton College, Bristol. Mr. Rodwell enters upon his new duties at the commencement of Michaelmas term.

The Educational Lectures delivered at the London Institution during the past session, by Professor Huxley, Dr. Odling, and Mr. R. A. Proctor, were followed by examinations, and on Wednesday last the prizes and certificates obtained by the students were distributed by Thomas Baring, M.P., F.R.S., the President of the Institution. In Chemistry, the first prize was awarded to Frederick Garrett, and the second prize to A. J. Richardson. In Biology, Miss Dora Harris gained the first prize, while A. Percy Lloyd and Miss F. L. Tolmé obtained second prizes. In Astronomy, the first prize was gained by A. J. Wallis, and second prizes fell to Miss Annie Piper and Edward Garrett.

British Association for the Advancement of Science.—The next meeting of this Association is to be held at Edinburgh, and will commence on Wednesday, the 2nd of August, under the Presidency of Sir William Thomson, M.A., LL.D., D.C.L., F.R.S., &c. The facilities now afforded by the several Railway and Steam-Boat Companies to parties travelling from all parts of Great Britain and the Continent, render it probable that this meeting will be very numerously attended. The local authorities and the representatives of the various scientific societies, as well as all those officially connected with the association, earnestly desire that the members and Associates should receive a cordial welcome, and that everything possible should be done to make the visit agreeable and instructive.

British Association of Gas Managers.—The Eighth Annual General Meeting of the members of this Association will be held on Tuesday, Wednesday, and Thursday, the 13th, 14th, and 15th of June, 1871, at the Royal

Dublin Society's Rooms, Kildare Street, Dublin. Edward White, Esq., Vice-President, will occupy the chair. *Order of Proceedings*.—Tuesday, at eleven o'clock, Inaugural Address by the Vice-President, and Reading of Papers and Communications; at seven p.m., Lecture by Dr. Letheby on "The Analysis of Gas." Wednesday, at eleven a.m., Reading of Papers and Communications, Election of Officers for ensuing Year, &c.; at six p.m., the Members and Friends will dine together at the Ancient Concert Rooms, Dublin. Thursday, Excursion to Glendalough, to visit the Lead and Silver Mines, and other places of interest in the neighbourhood. *List of Papers and Communications to be submitted to the Meeting*.—Report of the Committee on the establishment of a Benevolent Fund and the Reduction of Sunday Labour. "Lithology of Gas Coals," by Mr. Jas. Paterson, Warrington; "On the Best Form of Condenser," by Mr. W. J. Warner, South Shields; "On a New Equilibrium Gas-Governor," by Mr. Chas. Hunt, London; "On the Economy of Employing Exhausters," by Mr. Geo. Anderson, London; "On the Apparatus for and Method of Manufacturing Sulphate of Ammonia, suitable for small Works," by Mr. Jas. Eldridge, Richmond; "On the Cause and Prevention of Choked Ascension-Pipes," by Mr. John Somerville; "Carbonising Accounts," by Mr. W. J. Warner, South Shields; "Carbonising Accounts," by Mr. John Niven, Clayton; "Coal Storage and Spontaneous Combustion of Coals," by Mr. A. H. Wood, Hastings; "Spontaneous Combustion in Coal-Stores," by Mr. A. C. Fraser, Middlesbrough; "On Gas Measurement," by Mr. F. W. Hartley, London; "On the Manufacture of Gas from Coal-Tar," by Mr. J. Arnott, Leeds; "Additional Experience of Tar Pavement," by Mr. G. Anderson, London.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 8, 1871.

From the protocol of the meeting of this Society held on the 8th of May last, we learn that it is intended to submit to the approval of an extraordinary meeting of the members a proposal of the Council concerning the publishing in separate numbers of a large number of memoirs sent into the Society, the extent and length of which essays prevents them being published along with the *Berichte*. This number contains the following original memoirs and papers:—

Derivatives of Phosphuretted Hydrogen which Correspond to Ethylamine and Diethylamine.—Dr. A. Hofmann.—The eminent author describes, in this exhaustive essay, another series of researches belonging to those mentioned in former papers on this subject, and treats, in this instance, on—Monoethyl-phosphine—

a very mobile liquid, colourless, insoluble in water, highly refractive specifically lighter than water, boiling at 25°, very strong odour, bitter taste, very readily oxidisable, bleaching cork as chlorine does, acting strongly upon caoutchouc, which becomes transparent and loses its elasticity. When brought into contact with chlorine, bromine, or fuming nitric acid, ethyl-phosphine takes fire; it combines with sulphur and sulphide of carbon, forming liquid compounds therewith; combines, likewise, with concentrated hydrochloric, hydrobromic, and hydriodic acids, forming salts, the first-named of which forms a double salt with chloride of platinum, which, in its outward appearance, is quite as beautiful as crystallised chromic acid. Diethyl-phosphine,

* Containing nitrogen equal to 0.372 per cent ammonia.

† Corresponding to 2.31 per cent bone earth made soluble.

also a highly refractive liquid, insoluble in water, boils at 85°, absorbs oxygen with such rapidity as to cause, occasionally, the spontaneous ignition of this liquid. In most of its more prominent properties, this compound corresponds to that just alluded to. The author calls attention to the parallelism of the ammonia and phosphuretted hydrogen derivatives in the following manner:—

this very lengthy essay, commenced in No. 5 of this periodical, and recording an exhaustive series of experiments, may be summarised as follows:—By the action of chloride of sulphur upon aniline, the sulphide of carbon does not act as an indifferent solvent, but is an active ingredient; since, in the first place, 4 molecules of aniline, 2 of chloride of sulphur, and 1 of sulphide of carbon react upon each other according to the following formula:—

If more chloride of sulphur is used than agrees with the formula just quoted, that substance then causes the decomposition of the sulpho-carbanilide; but the sulphide of carbon does not, in this instance, come into active play, and the reaction takes place according to the formula—

Formation of Transparent Cubes of Chloride of Sodium similar to Rock-Salt.—Dr. L. A. Buchner.—This paper is, in a measure, the reproduction of the contents of an essay published by Dr. Mohr (*Poggendorff's Annalen*, vol. cxv., p. 667, 1868), "On the Formation of Rock-Salt." The author relates, in confirmation of the facts adduced by Dr. Mohr, a few instances which prove that the formation of cubes of rock-salt, and of other chlorides isomorphous therewith, actually takes place slowly by the spontaneous evaporation of concentrated brines and the gradual diffusion of the thus super-saturated solution downwards (in the vessel wherein that solution is contained), so that the cubes form, and increase gradually in size, at the bottom of the vessel which contains the saline liquor. The author also observed, in one instance, the formation of cubes of ammonium in cubical crystals deposited from the so-called Kœchlin's copper liquor (*Liquor cupri ammoniati-muriatici*), the evaporation having been caused by the not well fitting of the stopper; but this process had taken years to produce the cubical form of crystals of sal-ammoniac alluded to.

Structural Formulæ.—Dr. A. Claus.—A critical review on Professor Kolbe's lengthy essay on this subject, lately published in this periodical.

Researches on Hydrated Oxide of Iron.—Dr. E. Brescius.—After referring to the various formulæ given by a large number of authors to the hydrate of oxide of iron, the author records a series of experiments made with the view to ascertain the true composition of the hydrated oxides alluded to. It appears that, neither when dried over sulphuric acid, nor, also, when dried at 100°, until in each case no change of weight took place, did it possess the composition corresponding to the formulæ $Fe_2O_3.H_2O$, $Fe_2O_3.2H_2O$, and $Fe_2O_3.3H_2O$, which are quoted by various authors. The hydrates of the oxide of iron are, further, very hygroscopic, and, in addition thereto, may retain water mechanically. The author also found that the most stable hydrate he could obtain, $Fe_2O_3.2H_2O$, loses a portion of its water at 100°, and another portion only at a red heat. The composition of the hydrate which had been kept for fifteen months under water is not that which agrees with the formula given to it by Dr. Wittstein, $2Fe_2O_3.3H_2O$. The author is engaged with further experiments on this subject.

Dissociation Phenomena Exhibited by Aqueous Solutions of Chloride of Iron.—Dr. F. W. Krecke.—The first, and as yet incomplete, portion of an essay on this subject.

Zeitschrift für Chemie von Beilstein, No. 5, 1871.

This number contains the following original papers and memoirs:—

Isomeric Toluylene Diamines.—Drs. F. Beilstein and A. Kuhlberg.—This paper treats on the following substances:—Para-meta-toluylene-diamine, $mC_7H_4(NH_2)_2$.—This body, fusing at 99° and boiling at 280°, has been fully investigated and described by Dr. A. Hofmann (*Jahres. f. Chem.*, 1861, 512); the sulphate of this base, $C_7H_4(NH_2)_2.H_2SO_4 + 2H_2O$, is soluble in water, precipitated from its solution in that fluid by alcohol, and crystalline. Para-ortho-toluylene-diamine, $oC_7H_4(NH_2)_2$, is a solid body, fusing at 88°, boiling at 265°, and readily soluble in cold and hot water; but these solutions are spontaneously decomposed by exposure to air. The sulphate of this base, $C_7H_4(NH_2)_2.H_2SO_4 + 14H_2O$. Meta-ortho-toluylene-diamine, $moC_7H_4(NH_2)_2$, a solid body, colourless, crystalline, fuses at 80°, boils at 270°, and is very prone to spontaneous decomposition. The sulphate of this base, $C_7H_4(NH_2)_2.H_2SO_4$, is anhydrous, difficultly soluble in cold, but somewhat more readily in hot water; this solution is precipitated by alcohol.

Some Derivatives of Meta-Toluidine.—E. Wroblevsky.—The author describes a series of compounds obtained by causing various reagents to act upon pure meta-acetotoluid, viz.:—Brom-acetotoluid, $C_7H_4Br(NH.C_2H_3O_2)$, a beautifully crystalline body, fusing at 156°, and readily soluble in alcohol and boiling water. Brom-toluidine, $C_7H_4Br.NH_2$, fuses at 57°, boils (but is, also, then completely dissociated) at 240°, soluble in alcohol, but in water very difficultly; this base yields crystalline well-defined salts with hydrochloric, sulphuric, and nitric acids. *o-m*-dibrom-toluid, $C_7H_2Br_2NH_2$, is fluid, even at -20°, and boils at 287°. Dibrom-*m*-toluidine, $C_7H_2Br_2(NH_2)_2$, a crystalline substance, soluble in alcohol, fuses at 50°, and does not combine with acids. *o*-brom-*m*-kressol, $C_7H_3Br(OH)_2$, also a solid body, crystallises in golden yellow-coloured needle-shaped crystals, very difficultly soluble in water, as well as in alcohol, and fuses at 83°.

Chemistry of the Superphosphates.—Dr. K. Birnbaum.—This very lengthy paper is the first instalment of a monograph, the chief aim of which is to investigate thoroughly all the causes of the origin of the so-called reduced phosphates in superphosphates. This portion of the memoir contains a very detailed account of the result of the author's researches on the mono-calcium phosphate, its properties, behaviour towards reagents at a higher temperature, and on the di-calcium phosphate.

NOTES AND QUERIES.

Carbolic Acid.—Some information as to the finishing of carbolic acid, or phenic alcohol, into the pure crystals, would be most acceptable to me. I am now making, for another person, about 200 gallons of crude carbolic acid per week, but, as there is no demand for it, I have a chance to work it up.—W. G. HOLDING.

Nitrobenzol.—(Reply to "Mirbane.")—You will find every information on the subject in the work "On Aniline and its Derivatives" by M. Reimann, Ph.D., &c., revised and edited by W. Crookes, F.R.S., &c. (London: Longmans and Co.), page 6 and following. On the small scale, you can distil nitrobenzol in a glass retort placed in an oil-bath and provided with a Liebig's condenser.

MEETINGS FOR THE WEEK.

MONDAY, 12th.—Royal Geographical, 8.30.

TUESDAY, 13th.—Photographic, 8.

Ethnological, 8.

THURSDAY, 15th.—Chemical, 8. Sir B. C. Brodie, "An Experimental Enquiry as to the Action of Electricity upon Oxygen."

Royal, 8.30.

FRIDAY, 16th.—Royal Institution, 9. William Bradford, Esq., Artist, of New York, "On the Esquimaux and Ice of Greenland."

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

Just published, demy 8vo., with 42 woodcuts, price 14s.,

The Antiseptic System: A Treatise on Carbolic Acid and its Compounds, with an Inquiry into the Germ-Theories of Putrefaction, Fermentation, and Infection, the Theory and Practice of Disinfection, and the Employment of Antiseptics in Practical Medicine and Surgery. By A. E. SANSOM, M.D., London, M.R.C.P.

London: HENRY GILLMAN, Boy Court, Ludgate Hill, E.C.

Moniteur Scientifique, May 1 and 15, Nos. 345 and 346 (double number), 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Memoir on the History of the Discovery of Genuine (Véritable) Artificial Alizarine.—P. Alfreid.—This very lengthy and exhaustive memoir is divided into the following chapters:—Origin of our researches of this discovery (viz., of artificially-prepared alizarine); history of alizarine in madder (by MM. Robiquet and Colin, at Paris) up to the time of the synthetical preparation of alizarine; history of the more important pseudo-alizarines discovered before the genuine artificially-prepared alizarine was found. The author comes to the conclusion that the material obtained from anthracene is not at all identical with the alizarine obtained from and present in madder; and his reason for this conclusion is, that when alizarine from madder is oxidised with nitric acid, only phthalic acid is produced, not accompanied by any trace of bitter-tasted nitrated body of the phenic series, while alizapurine (the author prefers so to designate, or, also, call anthrazarine, the substance obtained from anthracene), oxidised in the same manner, yields always a large quantity of a bitter-tasted nitrated acid, only accompanied by a faint trace of phthalic acid. Lastly, the author states that he will shortly publish, in a subsequent number of this periodical, the mode of preparation of an artificially-obtainable alizarine, which is really identical with that of madder.

Although not belonging directly to the domain of physico-chemical science, we quote here the titles of the two following very interesting and valuable memoirs:—

Critical Observations on the Use of Words Derived from the Oreek Language in Scientific Nomenclature.—Dr. Egger.

Observations on Words Derived from the Arabic Tongue.—Dr. L. A. Sédillot.—This memoir also contains a brief, but valuable, review of the influence exercised by the Saracens in Southern France, and other portions of Southern Europe, on civilisation and the diffusion scientific as well as industrial knowledge.

THE CHEMICAL NEWS.

VOL. XXIII. No. 603.

ON THE ABSORPTION OF SULPHUR BY GOLD, AND ITS EFFECTS IN RETARDING AMALGAMATION.*

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

A PART of the duty assigned to me while recently on the Thames gold-field, was to investigate into the causes of the loss of gold experienced by the proprietors of the several batteries in that district, when working the auriferous material.

From an acquaintance with the various mechanical arrangements adopted there for securing the gold, and from a knowledge of the nature and amount of such loss, I was soon led to infer that much of it could scarcely be referred to any of the causes severally supposed to be operative.

The affinity of gold and its richer alloys for mercury is so great, and their negativeness or unaffectedness to and by the various chemical substances naturally having contact with them so universally and so authoritatively affirmed, that it is generally supposed all we have to do in order to obtain an amalgam of gold and mercury is to present them to each other, with their surfaces free from dust or stain, and to all appearance chemically clean.

But, in experimenting upon a few samples of the Thames gold, I found that though apparently quite free from any such stains, &c., they would not uniformly amalgamate over their entire surfaces; some, indeed, would not amalgamate in the least, though to all appearance bright, clean, and chemically similar to those which did; the action of boiling water upon these did not in the least affect their negativeness to the mercury. This could not, therefore, be owing to the intervention of air mechanically adherent to them.

Observations taken since my return show, besides, that several of the cleanest-looking samples of the Otago gold which have been deposited in the Colonial Museum, manifest a similar negativeness to mercury—even to whole samples of fine alluvial gold, and those surfaces of small nuggets so situated that it was impossible they could have been hand-soiled.

All these specimens were rendered readily amalgamable by cold solutions of cyanide of potassium, nitric acid, chromic acid, or chloride of lime acidified, and, with the exception of the more cupreous of these, they were also rendered amalgamable by roasting them in an open fire for a few minutes.

Obviously, therefore, some foreign substance occupied these non-amalgamable surfaces, excluding the mercury from contact with the auriferous alloy, which substance was dissipated or decomposed by heat, and capable of removal by the several reagents specified; the question then arose, What could this substance be? and I began to suspect that sulphur, in some form or other, was this substance, since its deportment under these conditions would certainly be very similar.

I therefore well cleaned the surfaces of several samples of Thames and Otago gold, and one of pure gold, and placed them for a few seconds in sulphuretted hydrogen gas, well washed them afterwards, and dipped them into clean mercury, when, in the place of being instantly whitened over their whole surfaces by the mercury, they absolutely refused to amalgamate with it upon any part, and even seemed to exercise a repulsive force upon it.†

The same effects, or rather *non-effects*, in relation to the

mercury, followed when alkaline sulphides were substituted for the sulphuretted hydrogen, also when the samples of gold were kept a short time in boiling water, in contact with sulphur—a platinum crucible being used as a precautionary measure against the introduction of alkaline matters. As in the case of the first series of specimens, these were rendered amalgamable by treatment with cyanide of potassium, nitric acid, chromic acid, or chloride of lime, also by the application of heat to the less cupreous ones.* The effects of heat on those samples containing 6 per cent of copper (and perhaps much less) being to produce such a film of the oxide upon their surfaces that the mercury is still excluded from them, though from a different cause from that above mentioned. These samples also readily amalgamated with sodium amalgam.

Gold thus treated with sulphuretted hydrogen, sulphur, or alkaline sulphides, and thoroughly washed, then put in pure cyanide of potassium, gave a good reaction of sulphur to the nitro-prusside test; and I have also obtained in the same manner, very distinct reactions of sulphur upon several of the native gold samples in the Museum.

These results clearly show that gold, even when in its purest state, is by no means so negative to sulphur and its compounds as is supposed, but that, on the other hand, it absorbs sulphur with great avidity; and they further show, that when this sulphur is absorbed by gold, even when only in very minute quantity, the metal refuses to amalgamate, although there is no visible change induced in its appearance.

Taken in connection with the presence of sulphur (or a compound of it) upon many samples of native gold, and the certainty that one or other of the sulphurising agents specified does frequently occur naturally in metalliferous rocks, it seems highly probable that a large area of the natural surfaces of native gold is sulphurised, and thus rendered, according to the degree of this, non-amalgamable.

If this is so, a very sufficient cause appears for the heavy loss in the precious metal experienced by the mill-owners in working their auriferous reefs by the amalgamation process, since it would only be those portions or grains thus sulphurised, which have chanced to get their surfaces abraded during their extraction or milling, that would be at all likely to adhere to the mercury used.

Whether this absorption is a purely mechanical one, as is assumed when platinum acts upon sulphuretted hydrogen and other gases, or whether it is a truly chemical one, is a matter of some interest to enquire into, particularly in connection with the, as yet, unsolved problem relative to the mode of solution and deposit of native gold; also, in relation to the question of absorption generally.

By what can properly be deduced from the facts above stated, and those which have manifested themselves to an investigation carried on especially to determine this point, it certainly appears that this absorption is the effect of chemical action.

Thus, if this absorption is mechanical, the sulphur must be in one of the two following conditions:—

I. As free sulphur.

II. Combined with hydrogen, as sulphuretted hydrogen.

(1). That it is not as free sulphur was evidenced by the fact that boiling ether or bisulphide of carbon—two liquids having considerable affinities for sulphur—would not remove it from the gold; for, after long contact with these solvents, and an after thorough washing, the gold still refused to amalgamate.

Neither of these liquids had any effect upon clean gold in regard to its behaviour with mercury.

(2). That it is not combined with hydrogen, and thus condensed on the gold surface as sulphuretted hydrogen, appeared from the circumstance that sulphurous acid effected no apparent change on it; the action of this acid

* Read before the Wellington Philosophical Society.

† This was illustrated at the close of the meeting.

* The chlorides of gold and mercury, also nitrate of silver, have been found lately to have the same effect. See paper "On the Reduction of various Metals from their Solutions by Metallic Sulphides, &c." C. N., vol. xxiii., p. 32).

on sulphuretted hydrogen being a rapidly decomposing one, sulphur being liberated in a free state, capable of being detected and identified as in this state, which I could not accomplish.

Not appearing to be in either of these forms, therefore we must assume it to exist in chemical union with the metal as a sulphide of gold, forming a film of true auriferous pyrites, as was first suggested to me by Dr. Heclor.

Independent of the proof derived from experiment, it may be expected that sulphur brought into close contact with a metal which we know does form chemical union with it in a wet way, and at common temperatures, would then be in an extremely favourable condition for the exercise of chemical affinities; and the same argument applies for absorption being generally chemical, wherever there are affinities existing at the temperatures we employ between the absorbants and the absorbed substances.

Indeed, so far these experiments and these arguments are deemed conclusive in favour of the absorption of sulphur by gold being chemical, by so much are we compelled to diverge from the received opinion that the absorption of the common gases by platinum is always a mechanical one, and are compelled to distinguish varieties of absorption.

The affinities of sulphur, also oxygen, for platinum, are superior to their affinity for gold; why not therefore suppose sub-sulphides, or sub-oxides, to form, when these substances are respectively absorbed; but the whole question of these minute actions of metallic surfaces requires rigorous investigation, and for this I doubt not the mercury test here used for proving absolute cleanliness of surface will often prove very useful.

Reverting to that which more strictly falls within the scope of this paper, as sulphur has been found upon native gold, I should be quite prepared to find the metals tellurium and selenium also upon the natural surfaces of the gold of Transylvania and the Thames (these substances being isomorphous with sulphur and more fixed), as telluric gold is found in Transylvania, and the character of the two golds assimilates.

In conclusion, I would beg to observe the necessity of fully establishing the character of this absorption of sulphur by gold. If it is a chemical act, as present evidence tends to show, and sulphides of gold and platinum are so easily and so rapidly formed, we cannot doubt but that sulphur plays a very important part in the solution and translation of these metals from rock masses to intersecting quartz reefs, or from deep strata to superficial positions.

In whatever form, however, sulphur is thus absorbed by gold, it is certainly the greatest obstacle to a thorough and complete amalgamation which we have to contend with; no doubt other substances occasionally intervene to prevent or retard this process, such for instance as the oxides of iron and organic matter, but sulphur and its isomorphs must, I think, be the most actively and the most frequently concerned in this refusal of natural gold surfaces to amalgamate. In case further investigation should prove this sulphurisation of the natural surfaces of gold to be general, it will be easy to look for a remedy against its effects; but, as yet, it would be useless to speculate as to what this should be. As stated, there are several ways of removing these films: perhaps chloride of lime in conjunction with muriatic acid would prove serviceable, but, unfortunately, it could only be applied to the "stuff" before amalgamation, and there might be a loss of gold occasioned by solution.

The sodium amalgam of Crookes would be a safe and certain remedy, and easily applied; its effect would be in relation to this sulphide, to decompose it, and so expose the encrusted gold to the action of the mercury.

Doubtless the great benefit which has often attended the use of this amalgam has been principally due to the exercise of this kind of action.*

SUGAR FROM MELONS AS COMPARED WITH SUGAR FROM BEETS.

MR. W. WADSWORTH, in a letter to the *Sacramento Union*, maintains that sugar can be made more profitably from melons than from beets. He says:—

The sugar from cane, maple, beets, parsnips, the sweet-gourd, and all the varieties of melons, when manufactured perfectly pure, are chemically identical. In Hungary and Italy there are numerous large establishments for the manufacture of melon sugars. The cost of melon sugar as compared with beet sugar is in favour of the melon. Every German or French authority on the culture of beets for sugar, admits the necessity of two, and recommends three, deep and thorough ploughings of the land to properly fit it for the culture of beets. With melons it is quite otherwise. To secure the largest yield and best beets, the seed should be planted in rows two feet apart, and from eight to ten inches apart in the row. For beets, all the land—for illustration say fifty feet in width—must be ploughed at least twice. For melons, only four beds, twelve feet apart and each only four feet wide, or sixteen feet in width of ploughed land, against fifty for beets, will need ploughing.

The great expense of beet culture is in the hand-hoeing and weeding of every row, and in most lands as many as three of these weedings are required in a season, before the leaves are large and spreading enough to keep down the weeds. The difference between the weeding of four rows of melons and twenty-five rows of beets is very considerable; whilst the exhaustion of the fertility of the soil is in the same proportion. With both crops the land between the rows is kept free from weeds with the horse-hoe or cultivator, at the same expense. Young melon plants are not as tender and delicate for the first eight days as beets. It is evident, therefore, that the expense of culture is largely in favour of melons, it being less than one-third the cost of beets per acre.

In gathering the two crops the difference is again in favour of melons, for they only have to be picked from the vine and thrown into carts; then, without washing or any other process, are ready for the mill. Beets must be first pulled, thrown into heaps to protect them from the sun, then each beet must be handled in having its crown of leaves and rootlets cut off, and then, before it is ready for the rasp or cutter, must be washed thoroughly clean.

The gathering and handling of melons is an agreeable and cleanly operation compared with that of beets. Large quantities of melons in certain localities can be sold for direct consumption in the early part of the season, or whenever worth more in that way than for sugar, spirits, or vinegar; it is not so with beets. Sugar making can commence a full month earlier from melons than from beets, and with winter water melons, as in Hungary, continued as late as with beets. Melons yield their seed every year with no extra expense for cultivation. Beets require a second year, with land, and careful culture and gathering of the seed. Melon seeds will yield sixteen per cent of their weight of excellent table oil. Beet seeds, beyond what are needed for seed, are of no value. The oil from the surplus seeds of melon sugaries in Hungary pays one-half the cost of cultivating the entire melon crop. The yield of melons per acre, in favourable soils, is equal to that of beets. The yield of sugar is as seven per cent from melons to eight per cent from beets; but the cost of manufacture is decidedly in favour of melons; they require less time, less bone-black, less machinery, less power, and less fuel, because no water is added, which cannot be said of beet juice by the ordinary process of extraction.

The natural purity of the juice of melons is so superior to that of beets, that whilst the melons furnish an agreeable "food and drink," and a delicious sweet, the juice of

* For further discussion on this subject, see *N. Z. Geol. Survey Reports*, 1870, p. 70.

beets is so acrid and herbaceous to be wholly unpalatable. The defecation and refining processes for melon juice and sugar are therefore attended with far less trouble and cost. That part of the beet which in many instances grows above ground, exposed to the sun, is of little or no value for sugar, whilst the hotter the sun and the drier the air, the better and sweeter the melon. The larger the sweeter generally, whilst the reverse is true of beets.

Beet juice and pulp exposed to the air, will turn black in fifteen minutes, and fermentation commences immediately from the rasp. Melon juice and pulp will not blacken at all, and will not begin to ferment in the open air before the third day from the melon. Beets are remarkable for their power of extracting alkaline and saline substances from the soil, which injures their value for sugar. Melons are equally remarkable for letting these salts entirely alone in the soil.

No centrifugals or presses are required to separate the juice from the pulp, as with beets; but all except the rinds and seeds go into the defecating kettles together. Cloth filters, concentrators, and a vacuum pan are as necessary as for beets. The buildings are less costly, because requiring less strength to hold in position the centrifugals and other necessary machinery for beet sugaries. The chemical processes of melon sugar making do not differ materially from those for the making of beet sugar, except in their simplicity. Spirits in large quantities can be extracted from the fermented juice of melons and the refuse of the sugarie, and "pure cider vinegar" is made therefrom in ten hours that cannot be distinguished from the genuine article. The melon rinds, with dry grass or straw, make an excellent food for milch cows.

USES OF INFUSORIAL SILICA.

INFUSORIAL silica is now employed as a substitute for heavy spar, in the manufacture of certain kinds of rubber goods. As india-rubber will float on water, it is desirable to have something to add to it that is lighter than heavy spar, and the silica seems admirably adapted to take the place of the heavy earth. By mixing three to six parts of infusorial silica to one part of freshly burnt lime, and stamping the whole, after slightly moistening it, into a suitable mould, artificial stone of any desired form can be made. Such stones become extremely hard, are impervious to water, are finer grained than cements or *béton*, can be used for gas or water pipes, and will take any colour. As there are large deposits of diatomaceous earth in various parts of America, this application for artificial stone and cement is well worthy of consideration.

By combining infusorial earth with native magnesite and chloride of magnesium, a cement is produced which is known in Germany under the name of albolith cement. The chloride of magnesium, obtained as an incidental product in salt manufacture, is very cheap in some parts of Germany, and the occurrence of large deposits of magnesite renders this variety of cement available in Europe for many purposes. A fine glaze for earthenware is obtained by fusing infusorial earth with crude borate of lime, or boronatrocalcite. A variety of porcelain can be made by fusing infusorial silica with the borate of magnesia of the Stassfurt mines. This kind of porcelain can be cast, pressed, and, if sufficiently thin, can be blown as easily as glass. It is capable of extensive use in the arts.

Infusorial silica is the best material for absorbing nitroglycerine, in the manufacture of dynamite, and is used for that purpose. Ordinary sand is not sufficiently porous. The ready solubility of this form of silica in soda suggests its application in the manufacture of liquid quartz. It is not a little singular that an earth which has long afforded test objects for microscopists, and has been employed as a polishing powder, should become an article of so much importance in the arts.—*Scientific American*.

ON THE ESTIMATION OF MANGANESE IN SPIEGELEISEN AND FERRO-MANGANESE.

By THOMAS ROWAN, F.C.S.

THE following process for the determination of manganese is, I need hardly say, not novel; but, having had occasion to make many estimations of manganese in spiegeleisen and ferro-manganese, I can recommend it as superior for speed and accuracy, where manganese in quantity has to be determined, to the other processes commonly resorted to.

A convenient quantity of the sample, say 20 grains, in as fine a state of division as possible, is digested in a long-necked flask, with about $1\frac{1}{2}$ ozs. of hydrochloric acid, until complete solution is effected. The solution is then oxidised with chlorate of potash added from time to time, and finally boiled until traces of chlorine can no longer be detected.

The solution is now saturated by liquid carbonate of soda added in small successive quantities, the flask being well agitated after each addition of the alkali. On nearing the point of saturation, each addition of the carbonate of soda occasions the separation of small quantities of carbonate of iron and manganese, which disappear on the flask being shaken. When this is observed the alkali must be added with extreme caution, but the deep blood-red colour now acquired by the solution will, after a little practice, be a sufficient indication to the operator that the desired point of saturation or neutralisation has been attained. Or, if it is preferred, the smallest excess of carbonate of soda may be added, and the permanent precipitate which forms re-dissolved by the cautious addition of hydrochloric acid, introduced drop by drop.

Before treating with carbonate of soda, the solution should be evaporated to as small a bulk as possible, the presence of much free acid causing the expenditure of an unnecessary amount of alkali, and the violent effervescence caused by the escaping carbonic acid often entails loss by the projections of portions of the solution from the flask.

From 6 to 8 ozs. of water are now added, and the iron precipitated as the basic acetate of iron, by the addition of a concentrated solution of acetate of soda. If the solution has previously been successfully neutralised with carbonate of soda, the ferric acetate will at once make its appearance; but if that point has not been reached, the iron will only precipitate after boiling, and then not completely, and the precipitate will be found to be so gelatinous as to cause much trouble by clogging the filter.

After the addition of the acetate of soda, the flask and contents are briskly boiled for about twenty minutes, and then allowed to repose for a few minutes, that the acetate of iron may settle to the bottom of the flask, when the solution is carefully decanted from it on a filter. More water is then added to the flask, with a few drops of acetate of soda, boiled for five or six minutes, and again decanted from the precipitate. This is repeated a third time. The acetate of iron can then be thrown on the filter and washed with boiling water. The filtrate, with washings, is removed to a beaker and brought to a temperature of about 100° F., and a stream of chlorine gas passed through until a faint smell of that gas can be detected from the liquid. This is ascertained by stopping, from time to time, the passage of the chlorine, blowing from the surface of the liquid in the beaker the gas that may have lodged there, and then testing by the smell. If chlorine can be detected the addition of the gas is finally discontinued. The beaker is now carefully covered and set aside in a moderately warm place for six hours. The precipitated binoxide of manganese is removed by filtration, and chlorine is again passed through the filtrate to ascertain whether all the manganese has

been removed. When the precipitated manganese settles to the bottom of the beaker, if the liquid above is purple-coloured it indicates that an excess of chlorine has been used, and that permanganic acid has been formed. This is easily remedied, as the permanganic acid is at once reduced to the binoxide by the presence of any organic matter. A few drops of alcohol may be added, and the precipitated binoxide of manganese filtered off.

The precipitated binoxide of manganese is re-dissolved by pouring hot dilute hydrochloric acid on the filter. The manganese is re-precipitated as carbonate by a solution of carbonate of soda, and boiled well to expel all carbonic acid, the carbonate of manganese being slightly soluble in carbonic acid. The carbonate of manganese is then collected on a filter, washed well with boiling water, dried, ignited, and weighed as the red oxide.

The binoxide of manganese has such a tendency to appropriate alkali that it cannot be directly ignited to the red oxide. When this is done without re-dissolving and re-precipitating as carbonate, I have found that one part of the ignited precipitate contains 0.0842 of alkali, which must be deducted from the weight before calculating the percentage of metallic manganese.

If the weight of the ignited red oxide thus obtained be 3 grains, the following calculation is made:—

$$\begin{array}{rcl} & \text{Wt. of red} & \\ & \text{oxide ppt.} & \\ 1 : 0.0842 :: 3 : 2.7474 \end{array}$$

In a rigorous analysis, however, it will be found more satisfactory to proceed as directed above, namely, re-dissolve the binoxide of manganese first obtained, and re-precipitate as carbonate before proceeding to ignite and weigh. The amount of metallic manganese is readily ascertained from the weight of the ignited red oxide, 100 parts of which contain 72.05 parts of metallic manganese.—*Engineering*.

A NEW METHOD FOR THE SEPARATION OF GOLD AND SILVER ON THE LARGE SCALE.

By Dr. F. GUTZKOW.

THE usual method employed on the large scale, for a considerable number of years, for separating gold from silver, copper, and other metals, consists in treating the alloy with concentrated sulphuric acid at a high temperature, and precipitating the silver from its dilute sulphuric acid solution by means of metallic copper, the desilverised liquor being used for the preparation of sulphate of copper. This, however, is in many respects deficient; for, in the first place, there is a large bulk of water required to dissolve the rather difficultly soluble sulphate of silver, and this large bulk of liquid requires, of course, large-sized vessels to hold it. Of far more importance is, secondly, the fact that it involves the production of a large quantity of sulphate of copper, a salt now obtained as a by-product in such large quantities, in various metallurgical and other operations, that, owing to its always yet rather limited consumption, this salt is very difficultly saleable. The manufacturer has, in most instances, to content himself with accepting a price for this article which often only barely covers the expense of the sheet copper employed and the copper present in the alloy which has been operated upon. Taking these matters duly into consideration, the author, who, while residing at San Francisco, in California, was for a series of years the manager of the extensive silver refining works belonging to the San Francisco Assaying and Refining Company, considered it to be of the highest importance to make a radical change in the method of silver refining just alluded to, and to limit the manufacture of blue vitriol to the comparatively small quantity of the copper contained in

the crude unrefined ingots. It was found unsuitable to substitute sheet-iron for the sheet-copper in the precipitation owing to the fact that, by the employment of iron, copper is, of course, again precipitated along with the silver; and the separation of the copper from the silver does not admit of any other method readily executed on the large scale than a repetition of the same process again. The author found, however, that the reducing agency of sulphate of iron (green vitriol) can be applied successfully to the solution of sulphate of silver. The process about to be here described has been employed for a series of years in the works above-named, and by this process several thousand hundredweights of fine silver have been produced. It should be observed at the outset that it is not readily possible, for reasons which are not here further alluded to, to work on the large scale with sulphate of iron upon the solution of sulphate of silver in water. On the contrary, it is required to prepare, first, crystallised sulphate of silver, free from impurities, inclusive of metallic gold in finely-divided state, sulphate of lead, and other substances, insoluble in a solution of green vitriol. The pure crystallised sulphate of silver is next to be acted upon by a hot and concentrated solution of green vitriol. The very hot, turbid, thickish fluid obtained by the action of boiling concentrated sulphuric acid upon the silver alloy under operation is poured into a large-sized cast-iron cauldron, containing dilute sulphuric acid at 58° Baumé=1.617 sp. gr., and previously heated to 110°; a small quantity of water is next added; and after the liquor (having been left at rest for a few minutes) has become clear, the solution is syphoned over into another similar cauldron, so placed and arranged as to admit of being thoroughly cooled by means of cold water externally applied. For every hundredweight of silver refined, 10 cubic feet of the dilute acid (sp. gr. 1.617) are taken. The addition of water just alluded to is intended to reduce the very concentrated acid silver solution to the same density, and the quantity of water to be added may be therefore inferred from this explanation. The addition of water is intended, however, to effect something else yet. Precipitates of sulphate of lead and sulphate of silver are formed, and the latter does not become quite permanent until, first, all the lead which was in solution is precipitated; and, moreover, these heavy precipitates greatly aid the throwing down of all substances which render the liquid turbid, and especially the gold. By the means just described, a clear liquid, quite free from any lead and gold, is far more rapidly and completely obtained than by the method usually applied—viz., the pouring of the very concentrated sulphuric acid silver solution into water.

The liquid, having been cooled in the manner just alluded to, and reduced to a temperature of from 30° to 40°, is, by means of a pump, transferred again to the upper cauldron, there to be used again as acid at 38° B. At the bottom of the cauldron in which the cooling took place the sulphate of silver will be found deposited, forming a hard, yellow-coloured, crystalline crust about 2 inches in thickness. This crystalline mass is tolerably free from adhering acid; but at the deepest part of the vessel will always be found some strongly acid mother liquor, and this acid is to be again used to dissolve a fresh quantity of silver. The crystalline mass, consisting of sulphate of silver, is removed from the cauldron by means of iron shovels, and placed on the perforated false bottom of a wooden box lined inside with lead, and placed on wheels, so as to be capable of being moved from one place to another; between the false and real bottom, a tap is placed for running off liquid. Along with the crystals, and adhering thereto, is a red powder, chiefly consisting of sulphate of copper. The next step is to run through, or, more correctly, pour over, the crystalline mass a very hot and very concentrated aqueous solution of protosulphate of iron (green vitriol). The salt of copper is first dissolved, and therefore that liquid is run off separately, afterwards to be used for the preparation of sulphate of copper. As soon as the solution which runs off begins to exhibit

the pure brown colour due to sulphate of peroxide of iron, the solution is caused to run into a large, very shallow vessel, in which, on cooling, the largest portion of the silver salt is decomposed, and some metallic silver is deposited in a spongy state, which substance is collected and placed on a large filter. The greater portion of the crystalline mass of sulphate of silver which had been placed in the box is, however, converted slowly on into a dense coherent mass of metallic silver, and the reduction may be considered complete as soon as the vitriol solution which runs off has assumed the green colour it originally possessed. The metallic silver is next washed with pure hot water, then pressed in a hydraulic press, and lastly melted.

The iron solution which has collected in the large-sized shallow vessel just spoken of, after having become sufficiently cool, is poured or run into a lead-lined tank wherein some scraps of old sheet-iron are placed, and is thus again re-converted into sulphate of protoxide of iron, to be used at a subsequent operation. The small quantity of silver and copper which are separated in the metallic state by this last-mentioned operation is collected from time to time, and put along with the crystals of sulphate of silver contained in the vessel, wherein they are to be exposed to the action of the sulphate of iron solution. The copper is almost immediately converted into sulphate of copper on coming into contact with sulphate of silver. On the large scale, for every hundredweight of silver reduced from the sulphate 20 cubic feet of green vitriol solution are required.—*Berichte der Deutschen Chemischen Gesellschaft zu Berlin.*

NOTE ON THE ANALYSIS OF MOLASSES.*

By M. A. VIVIEN,

Director of the Laboratory of the Association of Sugar Manufacturers, Paris.

M. DUBRUNFAUT published, in the number of the *Sucrierie Indigène* for June 20, 1870, p. 75, an article in which he tries to prove again that the methods pursued in the analysis of molasses, and considered hitherto exact, are false; from which it follows that all the results given by analytical chemists up to this time, and even until quite recently by himself, are and should be stigmatised as errors. If M. Dubrunfaut has proved what he advances, nothing is to be done but to suppress all chemists, for the manufacturers of sugar can no longer depend upon their dicta. But fortunately one cannot help seeing in this an exaggeration, which it is easy to reduce to the proportions of reality.

How has M. Dubrunfaut discovered that the method usually followed was false? In trying to determine the sugar in a molasses comparatively by a method of his own invention, and by that at present in use, he perceived that these two methods did not give identical results, and he concluded that the one in use was false and that the other was exact.

Still, whatever may be the authority attached to the name of M. Dubrunfaut, to his long experience in the matter, and whatever, on the other hand, may be my personal disqualifications, I do not hesitate to dispute his affirmation, and to call the attention of chemists to a doubtful point, the explanation of which is becoming so much the more urgent as the sale of molasses by analysis tends to become a general custom.

What is the method which M. Dubrunfaut recommends? A faint sketch of it is seen in the number of the *Sucrierie Indigène* for Nov. 5, 1869, p. 201, but the explanation is insufficient to be comprehended by every one; it is also necessary to trace the chemical reactions more minutely.

If I understand aright, the method which M. Dubrunfaut recommends is nothing other than the method taught by M. Jacquelin in the laboratory of the Ecole Centrale of arts and manufactures. The following is the method as taken from the laboratory book of the school:—

Determination of Glucose by the Alkaline Method.—In presence of alkalies and under the influence of a temperature of 100°C ., glucose has the property of uniting with alkalies, and consequently neutralising their effects; if then we boil a solution of glucose sugar with an excess of soda, it is only necessary to determine, by alkalimetry, the amount of soda which has not been neutralised, to find the quantity of glucose. Crystallisable sugar under the same conditions undergoes no change, and consequently does not saturate the alkali.

Composition of the Solutions—

No. 1. Soda solution (alkaline); 75 grammes of caustic soda are dissolved in distilled water; the solution is diluted up to one litre.

No. 2. Acid solution; 100 grms. of monohydrated sulphuric acid are diluted with distilled water up to the volume of one litre.

These two solutions neutralise each other volume for volume, and the titration is conducted in the following manner:—

Titration of the Solution.—Two grammes of pure dry sugar, to which is added 0.4 c.c. of fuming hydrochloric acid and a small amount of water, are kept for a space of 15 minutes at a temperature of 100°C ., easily attained and maintained by means of a water bath. The solution of inverted sugar is diluted to 200 c.c., and consequently contains 1 gramme of sugar in the 100 c.c.; 50 c.c. are taken, which are carefully neutralised with an alkaline solution, say of soda, then we add 10 c.c. of the test soda solution, and the temperature maintained at 100°C . Under these circumstances the glucose neutralises a certain quantity of soda; nothing more remains but to add the sulphuric acid solution in small portions at a time from a graduated burette, and to test, from time to time, by red litmus paper and a trace of the inverted solution, if the point of saturation is reached. The paper cannot be placed in the solution on account of the brownish chestnut colour, caused by the heat, masking every change of colour. To effect the saturation 7.95 c.c. of the sulphuric solution has been used, and 10 c.c. of the soda solution require 10 c.c. of the sulphuric solution; therefore the inverted sugar has saturated the same quantity of alkali that $10 - 7.95 = 2.05$ c.c. of sulphuric solution would take up.

Therefore, 1 gramme of sugar made uncrystallisable equals in acidity 0.41 gramme of H_2SO_4 . The solutions being titrated, the test of a molasses is as follows:—50 grammes of molasses, average sample, are dissolved in water and diluted to one litre; 50 c.c. of this solution are taken, which corresponds to 2.5 grammes of molasses; this solution should then be ascertained to be perfectly neutral, and then 10 c.c. of the soda solution is added. It is then kept at 100°C . for 15 minutes, and the alkalimetric test made. Suppose 8.1 c.c. of sulphuric solution were used, $10 - 8.1 = 1.9$ c.c.; therefore, 2.5 grammes of molasses contains a quantity of glucose equal to 1.9 c.c. of sulphuric solution, or, 100 grammes of molasses corresponds to 76 c.c., or we have $4.1 : 1 = 76 : x$; from which $x = 18.536$ per cent. Therefore, 100 kilos. of molasses contain in glucose what is equal to 18.536 kilos. of glucose sugar. To determine the quantity of sugar in an uncrystallisable state, 50 c.c. of the original molasses solution are again taken, to which is added 1.5 grammes pure HCl , and the solution kept for 15 minutes at 100°C . This is then carefully neutralised, 10 c.c. of the soda solution added, the temperature maintained as before at 100°C . for 15 minutes, and the alkalimetric determination made. Suppose it was necessary to use 5.8 c.c. of sulphuric solution, we then have $4.1 : 1 = 168 : x$; from which $x = 40.975$ per cent.

* Translated from the *Sucrierie Indigène* by E. Waller, E.M.

Then 100 kilogrammes of molasses contain—

40·975 sugar in all;
18·536 glucose.

22·430 in crystallisable sugar.

This method was taught some years since at the Ecole Centrale, and it appears to be the one which M. Dubrunfaut recommends and practises. Not only is it false, but it is very difficult of execution. We cannot judge without great difficulty of the exact point of saturation. M. Dubrunfaut, after having praised the saccharometric method, arrives at the conclusion that it is false, the results being varied by the presence of divers organic substances, and noticeably by that of asparagine. M. Dubrunfaut stopped there, and, in spite of his knowledge and perspicacity, he did not perceive that this asparagine falsifies the results if the alkaline method is used, even when taking sucrate of lime. This is what we are about to attempt to show.

A molasses, of whatever origin, is a solution of sugar, of mineral and organic substances. Certain organic substances can, under the influence of heat and prolonged boiling, decompose into multiple products, of which some are acids, and these acids by neutralising the alkali used will be reckoned as glucose. I will only take the case of asparagine, and this example will suffice to prove the fact which I advance. Under the influence of such an alkali as lime, and a temperature of 100°, the asparagine, a neutral body, changes to aspartic acid, with disengagement of ammonia. This reaction takes place during defecation in sugar refining, and is explained by the following formula:—

Asparagine. Aspartate of lime.

One equivalent of lime is therefore neutralised by an equivalent of aspartic acid, and the method advised by M. Dubrunfaut may indicate the presence of glucose in a solution which does not contain it at all. Is there any reason, then, to wonder that analytical chemists are unwilling to follow this mode of operation?

Since the question of the molasses analysis is on foot, I take the opportunity of describing briefly the method of analysis which I practise in order to submit it to discussion.

Every analysis should be made in duplicate, if one wishes to be certain of the figures which he gives; also the analysis of molasses should be made by two distinct methods, care being taken to work upon a sample which is very homogeneous. I operate in the following manner:—

MOLASSES ANALYSIS.

(1). *Formation of the Average Sample.*—All of the sample to be analysed should be passed through a sieve sufficiently fine to remove from it all foreign bodies, such as black grains, splinters of wood, straw, &c. It often happens that very dense molasses allows sugar to crystallise at the bottom of the bottles; taken hot from the filters it deposits the sugar in cooling, and if care is not taken to re-dissolve the sugar in the average sample its strength will appear too small. The molasses of M. Boulard, sugar manufacturer at Palinges (Saone et Loire), which gave occasion for the article of M. Dubrunfaut, was precisely in this condition, and if all the experimenters have not taken the precaution which I have just mentioned, they have naturally given figures too small.

First Analysis. Crystallisable Sugar.—16·35 grms. of the average sample of molasses are diluted in about 100 c.c. of water and clarified with—

(1). 10 c.c. of a solution of tannin.

(2). 30 c.c. of a solution of basic acetate of lead at 30° B.

The tannin precipitates the nitrogenous albumenoid substances, of which M. Dubrunfaut could not get rid; it precipitates also the salts of lime, and, moreover, the lime of sucrate of lime, the rotatory power of which

falsifies the indications of the saccharometer. The basic acetate of lead is employed in such quantity as to precipitate all the tannin, and to unite all the colouring matter which has not been eliminated by the tannin.

This clarification being terminated, the whole solution is diluted up to 200 c.c. It is then filtered and tested with the saccharometer. The number observed multiplied by 2 gives the amount of crystallisable sugar, excepting a correction which must be applied if there is too much glucose, in 100 kilos. of molasses.

Second Analysis. Total Sugar and Glucose Sugar.—50 grms. of the average sample of molasses are dissolved in water, rendered neutral by very alkaline tartrate of soda, and diluted to 500 c.c. Thus is obtained a first solution (A). This solution, filtered if necessary, is placed in a graduated burette, and run, drop by drop, into 10 c.c. of boiling copper solution of Trommer, Fehling, Barreswil, or others, to complete disappearance of the blue colouration (practice of M. Violette). This copper solution is sufficiently dilute to correspond only to about 0·005 gr. of sugar. 100 c.c. of the solution A is taken, acidulated with 20 to 25 c.c. of tartaric acid (25 per cent solution), the whole maintained at a temperature of 100° for 15 or 20 minutes and neutralised by soda. The solution thus inverted and neutralised is diluted to 1 litre. This solution B is treated in the same manner as has just before been done for glucose, but with a copper solution about ten times as strong. Suppose we have found 20 c.c. solution A to 10 c.c. of copper solution corresponding to 0·00575 of sugar; we have the proportion:—

20·6 : 0·00575 = 1,000 : x; from which x = 0·028 glucose, and 10·2 of solution B to 10 c.c. of the copper solution corresponding to 0·0575 gr. of sugar, we have the proportion:—

10·2 : 0·0575 = 10,000 : x; from which x = 56·37 total sugar. Finally, supposing that we have found by the saccharometer an observation oscillating between 27·75° and 28° which corresponds to 55·5 or 56, we take the mean and the analysis is interpreted as follows:—

	Per cent.
Crystallisable sugar	55·50
Glucose	2·28
Total sugar	55·78

The inversion by tartaric acid and the neutralisation by soda have the advantage of giving solutions which permit a thorough reduction of the copper solution without allowing at the end of the operation the colouring of the solution with a brown tint which might mask the indications of the final reaction, and prevent the formation of an annular precipitate, while all the sugar is precipitated. In operating thus, results are obtained agreeing within a degree at most; there is no need to seek for greater exactitude in a technical analysis of molasses. Moreover, for a difference of a degree the difference in selling value is much less than that which exists between two analyses of sugar made approximately to $\frac{1}{4}$ per cent—conditions accepted in commercial transactions in sugar. As every one can determine for himself the exactitude of these methods of analysis, I will finish this article by requesting M. Dubrunfaut to examine them and say for himself if he finds them exact; I claim at the same time, in return, his obligation to explain in all its details the method which he considers exact, for we, whom he accuses of being deaf to his advice, know nothing of it.

The 15th of March, 1870, he delivered to M. Monfourny a certificate of analysis of molasses thus expressed:—

The density of the molasses is 41° Baumé.

It contains in crystallisable sugar .. 37·600 per ct.
In actual glucose titrated by sucrate of

lime 4·016 ..

Total in sugar 41·616

Sulphatic ash 12·384 ..

In which lime forms a part to extent of 0·353 ..

The molasses is neutral to litmus paper.

The glucose determined by copper solution gives 7.692 per cent, which constitutes an error of 3.676 per cent more of fermentable sugar if this reagent, employed by many analysts, is used.

Signed, DUBRUNFAUT.

From this, it results that it is erroneous to use the copper method, but *now*, three months after, M. Dubrunfaut does not appear to be of the same mind any longer, since, he says:—"The percentage of sugar may be taken by the copper method, which is very sensitive. . . . We must reject the saccharometer, which gives figures radically inexact."

What conclusion must we come to? It would be well for the light to be established, and that M. Dubrunfaut, whose ability every one recognises, should assist us to do so.

Finally, I will express my regret that M. Dubrunfaut did not quote in full the certificates of analysis which he pretends are inaccurate. I have in my hands the certificate of MM. Laire and Galot. I only speak of this one, for I have not seen that of M. Zalinski, but I am inclined to believe that M. Zalinski diluted the molasses in such a way as to bring it up to 40° B.† which explains why he found so small a percentage.

Certificates as quoted by M. Dubrunfaut. Real certificates.

	MM. Laire and Galot.	M. Vivien.	MM. Laire and Galot.	M. Vivien.
Degrees Baumé,			41.5	42.05
Weight of 1 hectolitre,				
Crystallisable sugar, per cent	53.35	55.50	53.35	55.50
Glucose sugar, "	0.03	0.28	0.00	0.28
Total sugar, "	53.35	55.78	53.35	55.78
Ash, "	9.76	10.385	8.57	10.336
Which corresponds to a saline coefficient of "	5.46	3.34	6.22	5.34

Finally, in taking M. Dubrunfaut's figures as the only exact ones, I do not find a greater difference than 3.55 per cent (55.78—52.22), and not 8 per cent at all. In the same way, between 52.222 and 46.270, I find only a difference of 5.952 per cent, and not 11 or 12 per cent. It would be well, then, to know on what basis M. Dubrunfaut goes to establish the differences which he quotes.

LECTURE EXPERIMENTS.†

By Professor THOMSEN, of Copenhagen.

Reciprocal Combustion of the Elements of Water.

THIS may be demonstrated very instructively in the following manner. A pair of narrow platinum tubes, 1 centimetre long and 1 m.m. in diameter, are formed up of quite thin platinum foil. These tubuli are melted into a pair of small glass tubes, and are thus made the burners of the two gases, hydrogen and oxygen. The glass tubes are passed through openings about 1 to 1½ centimetres apart in an india-rubber cork. One tube is connected with the oxygen, the other with the hydrogen reservoir. After the cocks of the reservoirs are proportionately opened the hydrogen is ignited. The cork with its two burners is then inserted into a glass tube about 10 to 15 centimetres long, with its upper end much narrowed down, but still

left open. The entire apparatus has then the form shown in the following woodcut.

The hydrogen now burns in oxygen, the fusing together of the orifice of the glass tube being prevented by the end of platinum. If, now, the cock of the oxygen reservoir be slowly turned off, and the quantity of oxygen so diminished, the point is soon reached at which the supply becomes insufficient to support the combustion of the hydrogen; the hydrogen flame expands, then disappears for some moments, the flame appears at the oxygen burner, and now without any interruption the oxygen burns in hydrogen. If the oxygen cock be gently opened, the flame withdraws itself to the hydrogen burner, and again hydrogen burns in oxygen. The phenomenon can be repeated as often as desired without extinguishing the flame, provided that the increase or diminution of the stream of oxygen is not made too suddenly.

The experiment is highly captivating, and it is quite impossible for the observer who has not carefully watched it from the beginning to decide which of the two gases indeed is the combustible one. It shows the reciprocity

of the combustion in the clearest manner. It is evident that while the oxygen is burning an excess of hydrogen issues from the orifice of the large tube and can be ignited there, so that the combustion of hydrogen in the air, and that of oxygen in the hydrogen, can be shown at the same time.

Combustion of Oxygen with a Sooty Flame.

Heavy hydrocarbons, like benzol and oil of turpentine, burn with a very sooty flame; with a very similar flame oxygen also burns in the vapours of these bodies. The experiment is made in the following manner:—Some benzol is warmed to the boiling-point in a long-necked flask; the flask is closed by a cork with two holes, through one of which a glass tube of about 1 centimetre bore is passed, and through the other a tube somewhat narrower and bent to one side. When the vapour arrives at the orifice of the wider tube it is lighted, and then a tube, through which a slow stream of oxygen is flowing, is passed down into the flask through the flame. The oxygen tube is bent above, and its mouth is provided with a platinum tube fused into it. A cork upon the oxygen tube closes the wider tube of the flask. The benzol flame is extinguished, and the vapour issues through the side tube, while the oxygen burns in the benzol vapour with a very sooty flame.

Easy Demonstration of Oxidation and Reduction and their Accompanying Change of Weight.

Oxide of copper is rubbed together with some gum-water to a stiff paste, and made into a cylinder of about 1 centimetre in diameter and 3 centimetres in length. It is then dried, ignited, and reduced by hydrogen at a low temperature. The reduced copper has the form of a cylinder, is very porous, but, at the same time, is tenacious

* See last number of the *Sucrerie Indigène* (June 20, 1870), pp. 75—78.

† This practice is pursued in some laboratories.

‡ Translated by Prof. Leeds, from the *Ber. d. Deutsch. Chem. Gesell.* Communicated by the Editors of the *Journal of the Franklin Institute.*

enough not to fall into a powder. It is surrounded with some platinum foil, the end of which is fused into a glass tube. Two tubulated bell-glasses, connected by tubes with gas-holders, are now filled, the one with hydrogen the other with oxygen. The mouth of the hydrogen bell opens below, that of the oxygen above. The gases are now allowed to stream through the bells, the copper cylinder is made somewhat warm without allowing it to attain the point of ignition, and introduced into the oxygen bell. It forthwith ignites and continues to glow until its oxidation is complete. Then it cools off, and the light dies away. When taken out of the oxygen and put in the hydrogen bell it begins to glow fiercely again, much water condenses upon the sides of the bell, while the cylinder is reduced to metallic copper. We have here the highly interesting phenomenon of a body which burns twice in succession, first in oxygen and then in hydrogen, and both times with the same intense light and heat. After the second burning it is the same body as in the beginning. Since the change of weight in such a cylinder amounts to a gramme, the addition and subtraction can very easily be verified by a common balance.

NOTE ON THE

ANALYSIS OF CHROME-IRON ORE.

By J. E. STODDART.

IN "Select Methods of Chemical Analysis," page 54, is given a method for estimating chromium, by Professor Storer, which is said to be applicable to such compounds as chrome-iron ore.

This method consists in oxidising the chromium compound by means of nitric acid and chlorate of potassium; chromic acid is then formed, and estimated in the form of chromate of barium.

Being engaged in the analysis of chrome-iron ores, and this process seeming to promise good results in a short time, I made trial of it, under the direction of Professor Thorpe.

Half a gramme of the ore, pulverised to an impalpable powder, and then passed through very fine muslin, was heated with nitric acid and chlorate of potassium, in an evaporating dish as directed in the process. After an hour's heating, which is considerably longer than the time given by Professor Storer, there still remained some of the ore undecomposed, which after fusion with carbonate of sodium and nitrate of potassium, and treatment with boiling water, yielded a tolerably large precipitate of chromate of lead, on the addition of excess of acetic acid and acetate of lead.

This result seems to show that even after an hour's treatment with nitric acid and chlorate of potassium there still remains a pretty large amount of undecomposed chrome ore, and that therefore this method does not present any great advantage over the ordinary, although somewhat more tedious, process of fusion.

Laboratory, Andersonian University,
Glasgow.

NOTICES OF BOOKS.

Chemical Note-Book. London: S. Deacon, 30, King Street, Borough, S.E.

THIS useful work will be found a boon to pupils, as well as to teachers, especially by insuring uniformity in making notes of experiments. Its arrangement and intended use may best be shown by the reproduction, on a smaller scale, of one of its pages, which reads as follows:—

Description of Substance

Department of Solution with Reagents

Hydrochloric Acid.	Sulphuretted Hydrogen.	Ammonic Sulphide.	Ammonic Carbonate.	Sodic Phosphate.

Additional Experiments for the Detection of Metals

Experiments for the Discovery of the Non-Metallic Constituents

Name of Substance

Confirmatory Experiments

CORRESPONDENCE.

ATOMIC VOLUMES.

To the Editor of the Chemical News.

SIR,—As you have favoured me by the insertion in your issue of the 26th of May, of some brief remarks upon the doctrine of "atomic volumes," I may, perhaps, be permitted to offer a few additional observations in relation to it.

In further illustration then of my own humble views, I would call attention to marsh-gas, H_4C , as another well-known typical compound, formed of 1 volume of carbon-vapour, $\text{C}=12$, and 4 volumes of hydrogen, $\text{H}_4=4$, and, like the compounds to which I have before referred, viz., HCl , H_2O , and H_3N , presenting in the combination of its elements, a double product volume.

In this case, as the single volume of carbon vapour exists in equal proportions in each of the two compound volumes of H_4C , it follows, according to the reasoning in my previous communication, that it must be regarded as at least halved in the combination, like the single atomic volume of H and Cl, of O and of N, in the above compounds respectively. The atomic volume combining weight of carbon vapour would, in this point of view, be 6 instead of 12, as generally received. If, however, we consider more closely the constitution of H_4C , and bear in mind that the single volume of C, and the 4 volumes of H are not simply mixed, but *chemically combined*, in the condensed double compound volume, we can, I think, but conclude that an equal proportion of this 1 volume of carbon must be associated with each of the 4 hydrogen volumes; or, otherwise expressed, that the unit volume C is separated or divided into four in the formation of the product volumes H_4C , just as I have ventured previously to hint that the single volume of N is divided into three in H_3N . Should this deduction be correct, it will be necessary still further to divide the present atomic volume weight of C, and represent it by $\frac{1}{3}$, or 3, in lieu of either 12 or 6.

It is evident that a multitude of other compound gases may be viewed in the same light relatively to the *single* elementary volumes that enter into them, and that, accordingly, as I have presumed to infer, the atomic or combining weights of the elements should be regarded as strictly multiples of the true atomic volume weights. This theory is also supported by the fact that, in the case of mercury, Hg , 200, and of cadmium, Cd , 112, the atomic weights are *double* the respective vapour densities of those bodies.

I fear that I have already trespassed upon your valuable pages, and, therefore, will conclude in the words of one of our most distinguished chemists, Dr. Hofmann, "we are liable (speaking of bodies that he refers to) to be misled by analogy: to assume, for example, coincidence

of the combining weight with the volume weight, whereas, in truth, there may be, as in the cases of phosphorus and arsenic, no such coincidence, but an exceptional divergence; the combining weight corresponding to half the volume only, not to the full volume of the gas, or even, perhaps, standing in some less simple ratio thereto."—I am, &c.,

W. H. O.

Mildmay Road, Stoke Newington.

MAGNETIC CURVES.

To the Editor of the Chemical News.

SIR,—As I take great interest in lecture illustrations I was much pleased to read Dr. Mayer's article on the exhibition of magnetic curves. Would you allow me to say that a somewhat similar method to the one Dr. Mayer describes is in use by Mr. W. F. Barrett, of the International College.

Instead of using shellac, Mr. Barrett uses a solution of gum, which is allowed to dry on a piece of glass, and when the figures are obtained, they are fixed by breathing on the gummed glass. I would mention, too, that I have used, at Mr. Barrett's suggestion, the lantern I devised for cohesion figures with very satisfactory results. This lantern allows the slide to be horizontal, so that the actual formation of the curves is seen on the screen when the slide is tapped. One of my pupils, Mr. Anderton, used, some years ago, a similar method to that of Dr. Mayer, only instead of shellac as a cementing material, Canada balsam was used.—I am, &c.,

C. J. WOODWARD, B.Sc.

Midland Institute, Birmingham.

PALM OIL.

To the Editor of the Chemical News.

SIR,—If your space should permit it, will you allow me to append to the article on palm oil (by M. Gaston Tissandier), a few words, which, by preventing misapprehension, may render the information given more useful.

To many users of palm oil, the colour is of small importance, except in so far as it marks freedom from dirt and from some objectionable admixtures. Those who bleach the oil, look, I believe, not so much for an oil of deep colour as for one of bright colour. The brilliant orange-scarlet of fine Lagos oil is their desideratum. To makers of stearine, the "hardness" of the oil, that is, the proportion of hard fatty acids obtainable, is the important consideration.

I never saw a palm-oil adulterated with "fifty per cent of water." Parcels of oil occasionally come in, which give from ten to eighteen per cent of water, but these are classed with certainty under the head of "wet and dirty oil," and are very commonly valued with much accuracy by the samplers, who use no chemical test of purity, but simply inspect the samples when drawn. I think it would be difficult to induce a good palm-oil sampler to pass as "clean and merchantable" an oil containing ten per cent of water. But a mixture of two parts oil and one part water would need wonderful skill in mixing to render it passable as "clean."

To the notice of the oil, which may be expressed from the kernels of the palm nuts, it is desirable to add, that although it may be of "superior quality" in some points, yet it is quite different in character from the true palm-oil of commerce, which covers the outside of the nut as it grows. The palm-kernel oil is almost or quite useless for many purposes to which palm-oil is applicable. And an addition of the kernel-oil to the palm-oil, so far from raising the value of the latter, would lower this value

considerably to almost all ordinary consumers of the article.—I am, &c.,

W. H. H.

Belmont Works, Battersea.

MISCELLANEOUS.

Geologists' Association.—On the 2nd inst. an important paper was read at a meeting of this society by M. Hawkins Johnson, Esq., F.G.S., on the "Origin of Flints, and the Process of Silicification in General." After alluding briefly to the different modes in which these substances occur, the author proceeded to show that their formation is due to a chemical process which may be roughly expressed, in technical language, as the substitution of silicon for carbon. He pointed out how a crop of sponges invested with their gelatinous flesh or sarcode, and living at the bottom of a deep ocean, were suddenly buried in a thick stratum of white mud, consisting of the minute shells of *Foraminifera* that they then died, and while in the process of decomposition, this interchange of materials took place,—the nascent carbonic acid parting with its carbon in exchange for the silicon of the silicate of soda which sea-water is known to contain. At the close of the paper, the author produced a tadpole, upon which he had experimented, and which he had that afternoon subjected for two hours and a half to the action of nitric acid, without its undergoing any alteration, the inference being irresistible that the animal had become invested with a film of silica of sufficient thickness to protect it from the acid; another tadpole that had not undergone the same preparation having been converted into a brown cloud by immersion in the acid for the same time. The importance of this discovery in connection with the arts can scarcely be over-estimated; for the protection of perishable surfaces from decomposition is a desideratum that forces itself upon our notice daily.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Annalen der Physik und Chemie, von Poggendorff, No. 3, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Thermo-Chemical Researches.—Dr. J. Thomsen.—The continuation of a very lengthy monograph on this subject, this ninth section treating on the specific heat of aqueous solutions.

Experimental Optical Researches.—Dr. G. Quincke.—The concluding section of a lengthy monograph treating on Newton's coloured rings between surfaces of glass and metal.

Apparatus for Demonstrating the Axiom of the Parallelogram of Forces and the Laws of Equilibrium on an Inclined Plane.—G. Krebs.—A lengthy paper illustrated by several engravings.

Observations on the Theory of Capillary Phenomena.—A. Mousson.—An algebraico-physical essay illustrated with woodcuts.

Three Methods of Estimating the Resistance of Induced Currents.—Dr. F. Kohlrausch.

Reduction of the Second Axiom of the Mechanical Theory of Heat to General Mechanical Principles.—Prof. R. Clausius.

Limits of Applicability of the Law of Lenz-Jacobi.—Dr. A. von Waltenhoven.

Double Chloride of Zinc and Ammonium formed in Leclanché's Manganese Galvanic Element.—E. Priwoznik.

—This paper contains, in the first place, the detailed crystallographical description of the crystals just alluded to, illustrated by a woodcut. The composition of the crystals is, in 100 parts:—Zinc, 38.31; chlorine, 47.71; ammonia, 19.98. Formula, $\text{ZnCl}_2 \cdot (\text{H}_2\text{N})_2$. The chemical process by which it is formed in the Leclanché's cell is expressed by $2\text{H}_2\text{NCl} + \text{Zn} + 2\text{MnO}_2 = 2\text{H}_2\text{N} + \text{ZnCl}_2 + \text{Mn}_2\text{O}_3 + \text{H}_2\text{O}$.

Determination of the Temperatures of Fusion and Solidification of Fatty Substances.—Dr. Th. Wimmel.—This paper contains a critical review and observations on an essay on the subject just alluded to, published in this periodical (vol. cxi., p. 420) by Dr. F. Riidorff. The author of this paper states that fats exhibit two different temperatures of solidification (*erstarrungspunkte*)—one a natural, and another which might be termed artificial—the former of which, although not exactly coinciding with the fusion-point, is, at any rate, the most constant, and more readily determinable. The author points out the very great discrepancies existing between the various observations made by different authors on the fusion-point of the same kind of fat, adducing, as an instance, that beef suet, according to some authors, fuses at 37.6° , and, according to others, at 59.6° , and the same holds good for other fatty bodies, inclusive of Japan wax.

Observations on Prof. A. Heller's Memoir on Measuring the Intensity of Sound.—Dr. A. Seebeck.

Reply to Dr. Kennigott on his Remarks upon my Analysis of Chabasite.—Dr. C. Rammelsberg.—A vindication of the author's character against the insinuation made that he falsifies results of analysis.

Derivation (Ableitung) of the Behaviour of Gases towards Heat ($\frac{c}{c'}$) from the Mechanical Theory of Heat.—Dr. F. Mohr.

Description of a New Microscope Constructed by R. Winkel.—Prof. J. B. Listing.—It appears that the instrument here alluded to, made at Göttingen, is a masterpiece of good workmanship, the maker having especially taken care to guard against the deterioration of the lenses by the action of air and moisture, by reducing to a minimum the quantity of oxide of lead used in the composition of the glass the lenses are made of. In other respects, the instrument is not above those made by celebrated London and Paris microscope makers.

The American Journal of Science and Arts, May, 1871.

This number contains the following original papers relating to chemistry and allied sciences:—

Estimation of Phosphoric Acid.—C. E. Munroe.—Reserved for reproduction, an observation also applicable to the following paper, by the same author:—

Use of Porous Cones in Filtration.

Existence of the so-called Compound Ammonium-Almagams.—By the late Dr. C. M. Wetherill.—This paper contains, in the first place, an account of the results of the experiments made at various periods by different scientific chemists for the purpose of obtaining amalgams with the so-called compound ammoniums. Next follows the minute description of the preparation of methyl-ammonium oxalate by Lea's process; and, lastly, the author states that a portion of fluid sodium-amalgam, the size of a pea, was placed in a small test-tube ($\frac{1}{4}$ inch diameter), and the solution of methyl-ammonium oxalate added, the swelling was observed, both with and without shaking, in the cold and warm. The same experiment was performed with different specimens of methyl-ammonium oxalate; in some instances the swelling was from 3 to 10 times the original volume, which was very much less than the turgescence of the ammonium salt. The methyl-ammonium amalgam presented the same buttery appearance as the ammonium amalgam. When the lump was pressed between two plates of glass, myriads of gas bubbles were apparent; when these were pressed out, the amalgam was at once restored to the condition of mercury. A piece of filter-paper was placed upon a glass plate, then saturated with a strong solution of the re-crystallised methyl-ammonium oxalate; a globule of mercury the size of a small pea was placed upon the paper with the negative pole of twenty Bunsen cells in contact with it, the positive pole touching the paper; the globule of mercury swelled slightly, presented a buttery appearance, attached itself to and amalgamated the blade of a penknife which was in contact with the negative pole, and, upon being pressed under a glass plate, showed innumerable gas bubbles in its substance—in fact, was a metallic froth. It results from these experiments that the compound ammonium examined by this author may form the so-called amalgam.

This number also contains several valuable papers bearing upon natural history and geology.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, April, 1871.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

A Practical Method for Preparing Lactic Acid.—Dr. C. O. Harz.—This lengthy memoir contains a review of practical applicability of the various methods in use, and prescribed in pharmacopoeia, for the preparation of lactic acid. The author, after having made a series of experiments on this subject, found that, by using the following prescription, lactate of soda and other lactates may be readily prepared:—Take of milk sugar, 3 parts; water (not distilled, but good spring or river water), 360° ; a flour rich in gluten (the author has

successfully employed the well-known *farina hordei preparata*), from 0.50 to 0.75 parts; beer yeast, one or two large-sized table-spoonfuls; crystallised carbonate of soda, 6 parts, or bicarbonate of soda, 3 parts. The essay further treats, at length, on the mode of preparation of various lactates as required in pharmacy.

Action of Carbolic Acid and Creosote upon the Animal Organism.—Dr. Th. Husemann.—A lengthy, but valuable, physiological essay.

As a curiosity, taken from among the secret remedies, the analyses of which are quoted in this number, we copy the following:—

Lemonade for Strengthening the Memory.—G. M. Rauber.—The author puffs up, and sells for three shillings, a quantity of fluid, about 30 grms., containing 15 parts of phosphoric acid, 15 of glycerine, and 70 of water. This stuff is sold in Vienna.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, April, 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

Subjective Colours of the Double Figures (Doppelbildern) of Coloured Glass Plates, and on the Colours of Thick Plates.—Prof. Dove.—An optico-physical essay which, although of great value, does not admit of any useful abstraction.

Composition of Native Compounds of Niobium and Tantalum in General, and more especially on that of Tantalite, Columbite, and Pyrochlor.—Dr. C. Rammelsberg.—This monograph is divided into the following sections:—History of the discovery and earlier researches of the group of bodies alluded to; brief account of the labours of MM. Rose, Marignac, Blomstrand, Koscoe, and Deville on this subject; tantalite and columbite—older analysis; exhaustive account of the results of analysis of six different specimens of tantalite investigated by the author; analysis of several specimens of pyrochlor and columbite. This monograph is not quite complete; the author states that he will also publish his researches on fergusonite, ytthro-tantalite, euxenite, and other members of the tantalum group, and a general retrospective review of all these researches.

Bayerisches Industrie und Gewerbe Blatt, March, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Most Prominent Objects of the Industrial Exhibition held at Cassel last year, considered in a Technical, as well as Industrial, point of view.—Dr. E. Wiederhold.—The continuation of an excellent descriptive review, copiously illustrated with engravings, of the most useful and best-executed apparatus and tools intended for application in various ways; among these gas apparatus intended for use in localities where no large gas-works exist, or are near enough, occupy a prominent place, especially as regards the manufacture of gas from petroleum distillation, oil residues, and paraffin oil. Attention is also called to lucifer matches prepared entirely without phosphorus, either in the composition or on the paper intended for igniting them by friction. MM. Kalliwoda and Co., at Ortenberg (Grand Duchy of Baden), prepare a composition the essential ingredients of which are chlorate of potassa and hyposulphite of lead; the lucifer matches dipped with this composition ignite readily by friction on any rough surface, and are a little less costly than those containing phosphorus.

Recent Improvements made in the Wine Industry.—Dr. Ph. Neumann.—This lengthy memoir contains an excellent review of all that has been done of late years to improve the modes of making must, fermenting it, and all the novelties introduced to preserve wine by heating it, application of electricity, filtration, &c. We learn from this essay that in the wine-producing parts of Germany the manufacture of cognac from vine has become a profitable business, although the wines employed for this purpose are naturally less rich in alcohol than the French wines.

Annalen der Chemie und Pharmacie, May, 1871.

This number contains the following original memoirs and papers:—

Contribution to our Knowledge of the Sulpho-Nitrogen Acids.—Dr. A. Claus.—The continuation and end of this very lengthy and exhaustive monograph.

Normal Butylic Alcohol.—Drs. A. Lieben and A. Rossi.—Of this exhaustive monograph, the chief results were published in *Comptes Rendus*, vol. lxxviii., p. 1561. The following are the headings of the sections contained in this memoir:—Review of the labours of Drs. Wurtz, Chancel, Fayet, Kolbe, and others on this subject; preparation of butyraldehyde; butylic alcohol; oxidation of butylic alcohol; butylic chloride; butylic bromide; butylic iodide; butyl-ethyl ether; butylen; butylic acetate; butylic butyrate; butylic cyanide; butylamine; constitution of the normal butylic alcohol, and general observations. From the latter we quote the following:—If we compare the boiling-points of the now known four isomeric butylic alcohols together we find that the boiling-point of the tertiary butylic alcohol is the lowest, that of the normal butylic alcohol the highest, and that, starting from the first-named, the differences between the cyphers indicating the boiling-point decrease, as is exhibited by the following tabulated review:—

Normal butylic alcohol.	Fermentation butylic alcohol.	Secondary butylic alcohol.	Tertiary butylic alcohol.
$\begin{array}{c} \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \\ \\ \text{C} \\ \\ \text{H} \\ \\ \text{OH} \end{array}$	$\begin{array}{c} \text{CH}(\text{CH}_3)_2 \\ \\ \text{C} \\ \\ \text{H} \\ \\ \text{OH} \end{array}$	$\begin{array}{c} \text{CH}_3\text{CH}_2 \\ \\ \text{C} \\ \\ \text{H} \\ \\ \text{OH} \end{array}$	$\begin{array}{c} \text{CH}_3 \\ \\ \text{C} \\ \\ \text{CH}_2 \\ \\ \text{CH}_3 \end{array}$
Boils at—116°	109°	99°	82°
Difference—7°	10°	17°	

Normal alcohols may be defined as those which, of all isomeric alcohols, have—(1) The highest boiling-points, and are the most stable; (2) the simple and compound ethers of which, as, also, the amines thereof, have relatively the highest boiling-point, and the haloid combinations of which are least readily split up by the throwing off of CnH_{2n} ; (3) when oxidised, these bodies yield acids containing the same number of carbon atoms, and are distinguished from eventually (eventuellen) isomeric acids, by having a higher boiling-point and more power of resisting oxidation.

Investigation of a Himalaya Tea.—Dr. P. Züller.—This paper contains the results of a series of experiments made with a sample of very fine tea, a small quantity of which had been sent to Prof. J. von Liebig by a proprietor of tea plantations. 100 parts of the tea contained 4.95 of water and 5.63 of ash, which, in 100 parts, was found to consist of—Potassa, 39.22; soda, 0.65; magnesia, 6.47; lime, 4.24; peroxide of iron, 4.38; manganoso-manganic oxide, 1.03; phosphoric acid, 14.55; sulphuric acid, a trace; chlorine, 0.81; silica, 4.35; carbonic acid, 24.30. Extract soluble in water of this tea amounted to 36.26 per cent. The nitrogen in the air-dried tea was found to be 5.38 per cent. In addition to 4.94 per cent of theine, this tea was found to contain some theobromine. The quantity of nitrogen in the extract (that is, the portion of the tea soluble in water by infusion), dried at 100°, is 10.09 per cent, while the ash therein amounts to 11.46 per cent. The author concludes by stating that this tea is equal to the best Chinese tea, and that the younger the leaves of the shrub the better the tea they yield.

Decomposition of Acroline Ammonia by Dry Distillation.—Dr. A. Claus.—The result of the author's researches prove that acroline ammonia yields, by dry distillation, a volatile base, which is, however, while volatilising, partly decomposed. The crude oily product of the dry distillation yields, when submitted to distillation at from 120° to 150°, a volatile base (a new compound) which has a constant boiling-point, and is picoline.

Further Researches on Propargyl Ether.—Drs. C. Liebermann and O. Kretschmer.

Oxyphic (Styphnic) Acid.—Dr. J. Schreder.—The author, in the first portion of this lengthy memoir, proves the identity of styphnic acid, $\text{C}_6\text{H}_3\text{N}_3\text{O}_8$, with the trinitro-resorcin of Weselsky, the quantities of carbon and hydrogen in these substances having been found to amount, respectively, to 29.41 and 29.42 and 1.64 and 1.62. The memoir is further divided into the following sections:—Triamido-resorcin; hydrochlorate of amido-diimido-resorcin.

Basicity of Gluconic and Lactonic Acids.—Prof. H. Hlasiwetz.—The contents of this paper are mainly devoted to a critical review of Dr. Fittig's essay "On the Constitution of the so-called Carbohydrides," separately published under the following German title:—"Festschrift zur Feier des Geburtstages Sr. Maj. des Königs von Württemberg," Tübingen, L. F. Fues, 1871. However valuable the above-named paper may be, it is not well suited for abstraction, chiefly on account of the very large number of lengthy and complex formulæ which would require to be reproduced, an observation which equally applies to the two following papers:—

Formation of a Methyloisethionic Acid.—Dr. E. Erlenmeyer.

Lactic Acid contained in Muscular Tissue.—Dr. E. Erlenmeyer.

Polytechnisches Journal von Dinger, first number for May, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Observations on the Application and Caloric Statistics of Reverberatory Furnaces to Iron-Foundry Purposes.—Dr. E. F. Dürre.—A lengthy monograph of considerable value in reference to reverberatory furnaces in general, and the best mode of constructing them so as to utilise all the available heat of the fuel.

Henderson's Patented Method of Separating Phosphorus from Crude Cast-Iron.—P. Tunner.—Mr. Henderson's method, patented in New York, is fully described in the *Engineer* of the 17th of February last (p. 110). The author does not state anything new on this subject.

M. Kröncke's Method of Amalgamating Silver Ores, as used at Copiapo, Chili.—Dr. L. Eich.—The method alluded to may be summarised in the following manner:—The use of a hot and concentrated solution of protochloride of copper (*Kupferchlorür*) and common salt—the latter serving the purpose of keeping a larger quantity of the former salt in solution, and avoiding the formation of basic salts of copper. The use of perfectly dry and very finely ground up ore, so that the solution just alluded to may thoroughly penetrate; wet, or moist ore, moreover, causes the formation of basic salts of copper, and thereby loss of active protochloride of that metal. Use of lead and zinc along with mercury and the protochloride of copper, in such

quantities that the reactions take place according to the following formulæ:—

Lastly, the materials (ores) to be operated upon should always, as much as possible, be of the same richness and quality throughout.

Chemical Analysis of a Cement-Stone.—Dr. E. Reichardt.—The portion soluble in hydrochloric acid, amounting to 59.16 per cent, was found to consist of— CaO , 48.84; MgO , 26.96; CaO , 0.36; Fe_2O_3 , 3.83; FeO , 4.17; MnO , 0.22; Na_2O , 0.40; K_2O , 0.35; SiO_2 , 2.96; H_2O , 0.66. The rest, insoluble in hydrochloric acid, consists of— CaO , 0.76; MgO , 0.14; Fe_2O_3 , 0.60; Al_2O_3 , 1.60; K_2O , 0.13; Na_2O , 0.19; SiO_2 , 3.78; sand, 3.26.

Transparent Aniline Lakes and the Colouration of Mica.—F. Springmühl.—This paper treats, at great length, on the preparation of varnishes coloured with various aniline and other similar colours.

Method for Recovering Tartaric and Oxalic Acids from so-called Dischargers, and on the Use of Hypochlorite of Soda (Eau de Labarraque), instead of Bleaching Powder, as Discharge for Turkey-Red Dyed Fabrics.—Dr. A. Müller.

Sugar Refined with Sulphurous Acid according to Dr. Seyfert's Process.—Dr. P. Schulze.—This essay treats, at great length, on the effect of this process upon the refined sugar, as detectable by a peculiar taste and by its becoming yellow, and on the precautions refiners have to take when applying the sulphurous acid gas.

Valuation of the Quantity of Oil contained in Oil-Seeds.—Dr. H. Vohl.—A lengthy memoir, accompanied by the engraving of an ingeniously-contrived apparatus for the accurate estimation of the oil contained in various seeds.

Manufacture of Benzoic Acid from the Urine of Horses and Cattle on the Large Scale.—C. J. Kaufmann.—The author's exact process is not described, but, from 35,000 cwt. of urine, annually 70 cwt. of pure benzoic acid are prepared, which is chiefly consumed in England and France in the manufacture of aniline colours.

Method of Distinguishing Chloroform made from Chloral from Chloroform made from Alcohol and Bleaching-Powder.—Dr. Hager.—In the first place, the former chloroform, known now on the Continent as "English chloroform," has a sp. gr. of only 1.485, and contains, according to the author, from 0.75 to 0.8 per cent of strong alcohol. When, to the chloroform prepared from alcohol and bleaching-powder, strong sulphuric acid is added, it always becomes more or less coloured, which does not happen to be the case with the chloroform prepared from chloral; when, moreover, a few drops of each kind of chloroform are left to evaporate spontaneously upon a watch-glass, the chloroform prepared with alcohol gives off, after a while, a disagreeable smell, while the other kind retains until complete volatilisation its pleasant fruity odour.

Journal für Gasbeleuchtung und Wasserversorgung, No. 8, 1871.

This number contains, besides a series of papers strictly relating to gas and waterworks' engineering, the following information relating to—

Carboxygen Illumination.—Dr. J. Phillips.—The carbolin (the fluid used in the lamps invented by the author) costs about the same as petroleum—that is to say about 6d. per Prussian quart (1.145 litres). The hourly consumption of carbolin, amounting, on an average, to 30 grms., will cost about one halfpenny. As regards the price of the oxygen gas (an artificial air containing from 50 to 75 per cent of oxygen), it is stated that this may be prepared on the large scale at a cost of 15 centimes (2½d.) per cubic metre (a little more than 35 English cubic feet). The carboxygen illumination is daily gaining ground in Cologne, Brussels, New York, and other places. This light is also employed now in some large hot-houses where plants and shrubs are exhibited, the colours of leaves and flowers seen by this light being seen exactly as in daylight, while there is no danger of injuring the most tender and delicate plants, as there is with other artificial modes of lighting.

No. 9, 1871.

This number does not contain any other matter except what strictly belongs to gas and waterworks' engineering and management.

Les Mondes, March 23, 1871.

Recent unfortunate occurrences have caused a long delay in the transmission of this number, which, among a great variety of other very readable and excellent matter, contains the following, relating more particularly to chemistry and collateral sciences:—

New Plastic Material.—Rev. F. Moigno.—Very pure and very finely-pulverised phosphate of lime (bone-ash) is made into a paste by means of collodium. After having become dry, this substance becomes very hard, and assumes an excellent polish.

Collodium Prepared with Silk.—Rev. F. Moigno.—Pure silk is soluble in hydrochloric acid. If this solution is first neutralised by ammonia, and next evaporated at a gentle heat, the residue yields an organic chloride of ammonium suitable for photographic use.

Chemical Investigation of the Black-Coloured Matter of the Tadgerite.—Dr. S. Meunier.—By tadgerite is understood the stony matter which constitutes the meteorite fallen at Tadgera, near Sétif, Algeria, on the 9th of June, 1869. The author comes to the conclusion that the blackish colouration which obtains in grey-coloured

meteorites by the action of heat is due to the separation, in these substances, of a peculiar compound of peridotite nature; this separation is due to a kind of liquation of the silicates, especially those whereof the composition is akin to that of pyroxene and amphibole. The author calls attention to the fact that the heating to redness of a small fragment of meteorite may often give a precious clue to its mineralogical composition; so treated, for instance, the meteorite of Montrejeau exhibits irregular-shaped granules upon a whitish ground, which granules are not rendered manifest by analysis. The Pultusk meteorite exhibits colourless grains, which act strongly upon polarised light and are invisible before the stone is heated to redness.

Bulletin de l'Académie Impériale des Sciences de St. Petersbourg, vol. xvi., No. 1, 1871.

This number only contains the following original paper bearing on chemical science:—

Place of Cerium in the System of Elementary Bodies.—Dr. D. Mendeleef.—Since the value of this lengthy and learned memoir almost entirely depends upon the reproduction of a series of formulae, as well as upon that of a tabulated review of the system of the elements, divided and arranged according to the author's views into eight groups, each sub-divided again into ten typical series, it is not possible to give here an abstract of this highly scientific memoir, in which, moreover, several references occur relating to papers published by the author in the Russian language.

NOTES AND QUERIES.

Hydrate of Chloral.—Being anxious to make some pure hydrate of chloral, I shall be glad if you will inform me of the best and simplest method of making it, and purifying it when made?—W. E.

Disulphide of Carbon.—I should be glad if you or any of your correspondents would kindly tell me if the demand for disulphide of carbon is good; also, where the market is for the same, and what the price is per pound.—SULPHUR.

Estimation of Sulphur in Dense Coke.—Can any of your readers inform me of a good method for the estimation of sulphur in very dense coke? The methods I have tried do not yield very accurate results, on account of the high temperature required for decomposition.—S. REDDOP.

Carbolic Acid.—(Reply to W. G. Holding.)—To obtain the acid in dry state, recourse must be had to digestion with chloride of calcium, followed by a new rectification. If required pure, only that portion which boils at 370° F. must be received; the distillate, by refrigeration, furnishes crystals of the acid, which must be drained, dried, and preserved from the air.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

Chemical Technology, or Chemistry in its

Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannate, Fungate, Chromate, and Silicate of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prossiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

Now ready, price 6d.,

Notes of Professor Odling's Juvenile Lectures on BURNING AND UNBURNING, delivered at the Royal Institution of Great Britain, Christmas, 1870-71.

London: CHEMICAL NEWS Office, Boy Court, Ludgate Hill, E.C.

Just published, demy 8vo., with 42 woodcuts, price 14s.,

The Antiseptic System: A Treatise on Carbolic Acid and its Compounds, with an Inquiry into the Germ-Theories of Putrefaction, Fermentation, and Infection, the Theory and Practice of Disinfection, and the Employment of Antiseptics in Practical Medicine and Surgery. By A. E. SANSON, M.D., London, M.R.C.P.

London: HENRY GILLMAN, Boy Court, Ludgate Hill, E.C.

Royal 8vo., pp. 338, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling,

A Concise View of the Law connected with Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentee's Manual."

London: Longmans, Green and Co., Paternoster Row.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Casus's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under 4 per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under 4 per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

THE CHEMICAL NEWS.

VOL. XXIII. No. 604.

EXAMPLES FOR PRACTICE IN QUANTITATIVE ANALYSIS.

By ALEXIS A. JULIEN.

THE following examples in quantitative analysis are executed in the School of Mines, Columbia College. As the atomic weights employed in calculating the results of analyses have been corrected from time to time by more accurate determinations, I give at the outset the latest numbers.

TABLE I.—ATOMIC WEIGHTS.

H = 1.

O = 8.	O = 16.	O = 8.	O = 16.
Al 13.7	27.4	Hg 100.0	200.0
Sb 122.0	122.0	Mo 48.0	96.0
As 75.0	75.0	Ni 29.0	58.0
Ba 68.5	137.0	N 14.0	14.0
Bi 210.0	210.0	Os 100.0	200.0
B 11.0	11.0	O 8.0	16.0
Br 80.0	80.0	Pd 53.0	106.0
Cd 56.0	112.0	P 31.0	31.0
Cs 133.0	133.0	Pt 98.7	197.4
Ca 20.0	40.0	K 39.0	39.0
C 6.0	12.0	Rh 52.0	104.0
Ce 45.7	91.4	Rb 85.4	85.4
Cl 35.5	35.5	Ru 52.0	104.0

Mn 27.5	55.0	Zr 44.8	89.6

Strength of Reagents.

The reagents used in the laboratory are all prepared with the strength recommended by Fresenius in his "Manual of Qualitative Chemical Analysis." By the use of the following table, the amount of a reagent required for any precipitation can be readily calculated; though in actual practice it is generally advisable to employ a few more cubic centimetres, and also to add a few drops, first to the supernatant liquid, and afterward to the filtrate:—

TABLE II.

Dilute sulphuric anhydride, 1 c.c. will precipitate	0.231	grm. Ba
Barium chloride, " " "	0.032	" SO ₃
Disodic orthophosphate " " "	0.011	" Mg ₂ O
Magnesia mixture, " " "	0.024	" P ₂ O ₅
Ammonia molybdate, " " "	0.001	" P ₂ O ₅
Ammonic oxalate, " " "	0.016	" Ca ₂ O
Argentic nitrate, " " "	0.010	" Cl

Example No. 1.—Analysis of Fine Iron Wire.

Determination of Fe.—Weigh out from 0.3 to 0.5 grm. of the wire (previously rubbed bright with sand-paper).

Throw into a large covered beaker, add about 20 c.c. concentrated hydrochloric acid and heat until solution. Then add about 5 c.c. concentrated nitric acid, heat until the colour becomes a deep orange. The solution often becomes previously coloured to a brownish black, from the solution of nitric peroxide in protochloride of iron, but this is removed by longer boiling, and the orange colour finally appears. Rinse off the convex cover, dilute largely, add ammonia in excess, heat to boiling, allow to settle, pass the clear supernatant fluid through a five-inch filter, and wash by decantation several times, boiling the precipitate with distilled water. Finally throw on the filter and wash with boiling water, until a few drops of the filtrate, caught in a test-tube, and acidified with dilute nitric acid, give no reaction for chlorine on addition of a little argentic nitrate. Dry thoroughly, empty the precipitate into a weighed crucible, burn the filter completely on a platinum wire, and add the ashes to the crucible; ignite at first very slowly, and finally very strongly; cool in desiccator, and weigh. Repeat this ignition until the weight remains constant (within one milligramme). To determine the amount of silica in this precipitate derived from the glass beaker, empty the ignited precipitate into a small flask, add 10 c.c. concentrated hydrochloric acid, boil until solution, empty into a casserole, evaporate to dryness, again dissolve in concentrated hydrochloric acid, dilute, filter through a three-inch filter, dry, ignite in a weighed crucible, and weigh. This weight of silica thus found, corrected for the silica of the two filter ashes, is deducted from the previous amount; and, from the weight of Fe₂O₃ thus found, the weight and the percentage of Fe are readily calculated.

Example No. 2.—Analysis of Magnesic Sulphate.

A. Determination of MgO.—Dissolve 1 to 1.5 grms. in cold water, and add one-fifth its volume of ammonium chloride and sufficient disodic orthophosphate (see Table II.) Be careful not to rub the side of the beaker with the stirring-rod. Cover, and set aside twelve hours. Filter and wash with cold water, to which one-quarter its volume of ammonia has been added, until the filtrate, on being tested for chlorine with argentic nitrate, gives only a slight opacity. Dry and ignite as usual to constant weight. If the precipitate or ash is not perfectly white, moisten with a drop or two of concentrated nitric acid, evaporate and ignite cautiously, and repeat this operation to a constant weight. Result, Mg₂P₂O₇.

B. Determination of SO₃.—Dissolve 1 to 1.5 grms. in water, acidulate with hydrochloric acid, dilute largely, boil, add barium chloride in slight excess (Table II.); heat for a few minutes, allow to settle, and decant the clear liquid on a filter. Wash several times by decantation with boiling water; throw on the filter, wash thoroughly, dry, and ignite. Empty into a small beaker, digest with very dilute hydrochloric acid, filter, wash thoroughly, dry, and ignite. Result, BaSO₄.

C. Determination of H₂O.—In a weighed porcelain crucible weigh out 1 to 1.5 grms. Heat very gently at first over a low flame, to avoid loss by the ebullition of the salt, and finally lower the crucible until about an inch above the extremity of the flame. After heating thus about an hour, weigh, and repeat the operation until the weight remains constant. A portion of the acid may be expelled if the temperature is too high.

Example No. 3.—Analysis of Barium Chloride.

A. Determination of Ba.—Dissolve 1 to 1.5 grms. in water, acidulate with hydrochloric acid, dilute largely, heat to boiling, add dilute sulphuric anhydride in sufficient excess (Table II.), and continue as in Example No. 2. B. Result, BaSO₄.

* In order to make the student entirely dependent for accuracy upon his own skill and care, the substance given out for analysis in this and all subsequent cases is intermixed with known proportions (in several varieties) of certain inert salts, &c. So that while none of the determinations are affected by this intermixture, the student is entirely unaware of the percentages to be found.

B. Determination of Cl.—Dissolve 1 to 1.5 grms. in cold water; acidulate with nitric acid; add argentic nitrate in sufficient excess (Table II.); stir well; warm gently until the precipitate has completely settled; wash thoroughly with boiling water acidulated with nitric acid, at first by decantation, and afterward on a filter; and dry. Remove the precipitate as completely as possible to a weighed porcelain crucible, brushing the paper with a feather. Burn the filter on the cover and empty the ashes into the crucible. Moisten the whole with a few drops of concentrated nitric acid; digest 5 to 10 minutes; add 2 or 3 drops of concentrated hydrochloric acid; evaporate cautiously, and fuse at as low a temperature as possible. Result, AgCl.

C. Determination of H₂O.—Heat 1 to 1.5 grms. in weighed porcelain crucible, exactly as in No. 2, C. A portion of the chlorine may be expelled if the temperature is too high.

Example No. 4.—Analysis of Cupric Sulphate.

A. Determination of CuO.—Dissolve 1 to 1.5 grms. in a porcelain casserole, dilute, heat to boiling, add pure potassic hydrate to an alkaline reaction, and boil until the precipitate settles readily on the removal of the gas flame. Decant rapidly the clear fluid through a filter; wash two or three times by decantation with boiling water; transfer to the filter, removing as completely as possible from the casserole; wash thoroughly and dry. Empty the precipitate as completely as possible into a weighed porcelain crucible, burn the filter on the cover, empty the ashes into the crucible, and ignite strongly. As a trace of the precipitate generally adheres so firmly to the casserole that it cannot be rubbed off, dissolve it now in a drop or two of warm dilute nitric acid, and moisten the whole precipitate and filter ashes in the crucible (which may contain a little reduced copper), with this solution, and again evaporate and ignite cautiously, and at last strongly, to a constant weight. In this precipitate determine the silica derived from the casserole exactly as in Example No. 1. Result, CuO.

Concentrate the filtrate and washings from the original precipitate of hydrated oxide of copper, acidify with hydrochloric acid, and test with sulphuretted hydrogen water.

B. Determination of SO₃.—Proceed exactly as in Example No. 2, B.

C. Determination of H₂O.—Heat 1 to 1.5 grms. in a weighed porcelain crucible at 140° C., until the weight remains constant. Loss = 4 equivalents of water.

Heat again over the flame, as in Example No. 2, C, until the salt becomes white and the weight remains constant. Second loss = last equivalent of water. If the temperature be too high during the last heating a portion of the acid may be expelled: in which case a dark tinge, due to CuO, may be observed near the sides and bottom of the crucible.

Example No. 5.—Analysis of Silver Coin.

Clean with potassic hydrate, wash, dry, and weigh.

A. Determination of Au.—Dissolve in a little pure concentrated nitric acid, dilute, filter, wash thoroughly, dry, ignite in a porcelain crucible, and weigh. Result, Au + AgS. Wrap in a little pure silver, heat in cupel to fusion, cool, dissolve in nitric acid, filter, wash, dry, ignite, and weigh. Result, Au.

B. Determination of Ag.—Heat the first filtrate to boiling, add dilute hydrochloric acid in excess, and continue as in Example No. 3, B. Result, AgCl.

C. Determination of Pb.—To filtrate from B add to c.c. dilute sulphuric anhydride, evaporate to dryness, dissolve in warm water, filter, wash, dry, ignite in a porcelain crucible, and weigh. Result, PbSO₄.

D. Determination of Cu.—Heat to boiling the filtrate from C. in a casserole, add pure potassic hydrate in excess, and continue exactly as in Example No. 4, A. Result, CuO.—*American Chemist.*

THE NATURE OF DIFFERENT GUMS.

Dr. Sacc, of Neuenberg, Switzerland, has made an extensive inquiry into the nature of different resins. We condense from it the following results:—The resins spoken of are copal, amber, dammar, common resin, shellac, elemi, sandarach, mastic, and Caramba wax. All these resins can be reduced to powder.

The following will become pasty before melting:—Amber, shellac, elemi, sandarach, and mastic; the others will become liquid at once.

In boiling water, Caramba wax will melt; common resin will form a semi-fluid mass; dammar, shellac, elemi, and mastic will become sticky; while copal, amber, and sandarach will remain unchanged.

Dammar and amber do not dissolve in alcohol; copal becomes pasty; elemi and Caramba wax dissolve with difficulty; while resin, shellac, sandarach, and mastic dissolve easily.

Acetic acid makes common resin swell; on all the others it has no effect.

Caustic soda dissolves shellac readily, resin partly; but has no influence on the others.

Amber and shellac do not dissolve in sulphide of carbon; copal becomes soft and expands; elemi, sandarach, mastic, and Caramba wax dissolve slowly; while resin and dammar dissolve easily.

Oil of turpentine dissolves neither amber nor shellac, but swells copal; dissolves dammar, resin, elemi, sandarach, and Caramba wax easily, and mastic very easily.

Boiling linseed oil has no effect on copal, amber, and Caramba wax; shellac, elemi, and sandarach dissolve in it slowly, while dammar, resin, and mastic dissolve easily.

Benzol does not dissolve copal, amber, and shellac, but does elemi and sandarach to a limited extent, and Caramba wax more easily; while dammar, resin, and mastic offer no difficulty.

Petroleum ether has no effect on copal, amber, and shellac; it is a poor solvent for resin, elemi, sandarach, and Caramba wax, and a good one for dammar and mastic.

Concentrated sulphuric acid is indifferent to Caramba wax; it dissolves all resins, imparting to them a dark brown colour, excepting dammar, which takes a brilliant red tint.

Nitric acid imparts to Caramba wax a straw colour; to elemi, a dirty yellow; to mastic and sandarach, a light brown; it does not affect the others.

Ammonia is indifferent to amber, dammar, shellac, elemi, and Caramba wax; copal, sandarach, and mastic become soft, and finally dissolve; while resin will dissolve at once.

It is not difficult, by means of these reactions, to test the different resins for their purity.—*Dingler, Polytech. Journal.*

ON THE

EMPLOYMENT OF POTASSIUM FERRICYANIDE AS A TEST FOR COBALT, NICKEL, AND MANGANESE.

By ALFRED H. ALLEN, F.C.S.

In a former number of the *CHEMICAL NEWS* a correspondent called attention to the possibility of distinguishing cobalt from nickel by potassium ferricyanide, which he directed to be added to a solution of the metal after addition of tartaric acid and excess of ammonia. My former pupil, Mr. J. Spear Parker, while in my laboratory showed that the tartaric acid might be replaced by citric acid, or omitted altogether, any ammoniacal salt answering the purpose. Cobalt occasioned a deep red colouration, while with nickel no change occurred if sufficient ammonium chloride

were present. The reaction is delicate and trustworthy. I find, however, that a solution of nickel to which ammonium chloride, ammonia, and excess of potassium ferricyanide have been added, becomes turbid on boiling, and in a short time deposits the whole of the nickel as a copper red precipitate, which often adheres to the sides of the vessel. Thus the presence of nickel is readily detected by a simple test, which answers perfectly well even in the presence of a large excess of cobalt,—the latter metal being indicated at the same time by the red colour of the solution.

The red precipitate I at first supposed to be nickel ferricyanide, and to have the same composition as the gelatinous reddish brown precipitate produced by potassium ferricyanide on addition to nickel nitrate. This was rendered the more probable from a similarity of decomposition by boiling with sodium hydrate, which readily converts the nickel into a black precipitate (probably Ni_2O_3) with production of sodium ferro- and ferricyanides.

The brick-red precipitate does not contain sufficient nickel to correspond to either $\text{Ni}_2^{2+}(\text{C}_6\text{N}_6\text{Fe})^{4-}$, or $\text{Ni}_3^{2+}(\text{C}_6\text{N}_6\text{Fe})_2^{4-}$, and it evolves ammonia during the action of the soda.

I intend to examine this precipitate further, and to try and utilise it for the quantitative estimation of nickel, as whatever its composition may be, it is easily produced, easily washed, and readily decomposed into a definite compound by alkalis.

When a solution of manganous sulphate is treated with ammonium chloride and ammonia, and potassium ferricyanide gradually added to the solution so obtained, a whitish precipitate is first formed, which changes with the addition of more ferricyanide to a dark brown colour. This reaction is used in my laboratory to distinguish manganese from cobalt and nickel. The solution filtered from the precipitate contains ferrocyanide and ferricyanide, thus proving that the manganese has suffered oxidation at the expense of the ferricyanide. It is absolutely free from manganese, no green colour being developed by evaporation and fusion with alkaline carbonate and nitre. If the precipitate be boiled in the liquid containing excess of potassium ferricyanide, and then filtered from the solution, it is found to consist of a mixture of a higher oxide of manganese with manganous ferrocyanide; it yields by boiling with sodium hydrate, a black oxide of manganese and sodium ferrocyanide. The oxide of manganese thus obtained is entirely soluble in hot dilute HCl, with evolution of chlorine. There is a process described in the last edition of Fresenius where manganese is estimated by boiling the solution, in presence of iron, with potash and potassium ferricyanide, and then estimating the resultant ferrocyanide by standard permanganate.

I have employed the reaction of ferricyanide with an ammoniacal solution of manganese for the quantitative estimation of the metal, but do not think it possesses any advantage over the precipitation by bromine, if it be as good.

Manganese kept in solution by means of tartaric acid gives a similar reaction to the ammonium chloride solution, but the precipitation does not occur completely until the liquid is boiled.

In my practice it is frequently required to estimate the real manganese present in manganese ores—not the chlorine producing power—and also in spiegeleisen, &c., and this is often a tedious process, as the iron has always to be first separated, and the manganese requires to be very accurately determined.

In the above reaction there seemed a means of throwing down the manganese completely even in presence of iron, without the latter metal going with it, and with this view I mixed manganous sulphate with ferric chloride, added ammonium chloride, tartaric acid, and excess of ammonia, and then potassium ferricyanide. The liquid was then boiled for some time, but without any precipitate being formed, so the presence of iron is apparently fatal to the

process. With a smaller proportion of iron the manganese was partially precipitated, and the use of soda or potash instead of ammonia succeeded no better.

On treating a solution of zinc sulphate with excess of ammonium chloride and ammonia, and adding potassium ferricyanide, no change occurs either in the cold or on boiling, but if the heat be continued very long a slight white turbidity is occasioned, probably in consequence of the formation of a small quantity of ferrocyanide. On adding potassium ferrocyanide to either the hot or cold liquid, the zinc is thrown down as white zinc ferrocyanide, which is a far better and more delicate method of detecting it than the precipitation as sulphide.

Thus either one of the four metals, nickel, cobalt, manganese, or zinc can be readily distinguished from the others by adding first ammonium chloride and excess of ammonia, and then excess of potassium ferricyanide, when one of the following reactions will take place:—

- (1). A brown precipitate = manganese.
- (2). A deep red solution = cobalt.
- (3). No change in the cold—a copper red precipitate on boiling = nickel.
- (4). No change in either hot or cold liquid. Add potassium ferrocyanide—white precipitate = zinc.

As these four metals frequently occur in the same analytical "group," and in presence of ammoniacal salts, the above method of distinguishing them will, I think, be found useful, the only objection being that the explanations of the reactions are somewhat difficult, but I propose to study this question further.

I have not tried the reactions in the presence of any other metal except copper, which does not interfere with the test for nickel, and only by the colour with the reaction for cobalt.

The presence of manganese or zinc interferes with the tests for nickel and cobalt, which may prevent the reaction being used for the estimation of nickel in German silver, but I am still examining this question.

ON THE CAPABILITY OF CERTAIN SULPHIDES TO FORM THE NEGATIVE POLE OF A GALVANIC CIRCUIT OR BATTERY.*

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

WHEN a piece of massive galena is placed in voltaic contact with amalgamated zinc, and immersed along with it in weak sulphuric acid, to within an inch or two of the point of contact, a galvanic current is at once established, gas in quantity being given off at the surfaces of the galena, while the zinc is rapidly oxidised.

Three or four such pairs when connected among themselves, in series, afford a current of electricity strong enough to decompose acidulated water, and manifest all the phenomena of a small galvanic battery. Such an arrangement may properly be termed a *pyrites battery*—in accordance with the custom hitherto observed, of designating new forms of batteries after some distinguishing or novel feature in them.

Several other metallic sulphides manifest similar phenomena when coupled in this manner with zinc, amongst which are the following:—Zinc blende, copper pyrites, vitreous copper stibnite, proto-sulphide of iron, and the sulphides of silver, mercury, platinum, and gold.

The only sulphide I have yet found any difficulty with in setting up this action, under these conditions with zinc, is munda, or the bi-sulphide of iron; but if the point of contact between it and the zinc is submerged in the acid, gas is evolved at this point, and the area of evolution rapidly spreads around from this, until the whole surface of the specimen becomes active.

* Read before the Wellington Philosophical Society.

The gas given off from the surfaces of these sulphides in the foregoing experiments was *sulphuretted hydrogen*. The effects, therefore, upon these sulphides when thus made to form the negative pole of a galvanic pair, is to desulphurise them; in some cases the ultimate effect is to reduce the metal to the metallic state. At any rate this obtains for the sulphides of mercury, lead, silver, platinum, and gold. With common yellow copper pyrites, a beautiful iridescence is communicated to it in a few seconds after the liberation of gas commences, owing, of course, to desulphurisation.

Saline solutions appear to produce the same effects in these instances as sulphuric acid, but they take place much slower.

The fact is thus directly established, that several of the metallic sulphides are capable of performing all the functions of the negative pole of a galvanic pair. From this, and the manner in which these sulphides have been connected with each other, it is clearly demonstrated that they are pretty good conductors of electricity. To a certain extent, indeed, all bodies are conductors of electricity, the terms conductor and non-conductor being only expressive, as Faraday affirms, "of extreme degrees of one common condition," there being no complete conductor, nor any absolute non-conductor; but these results show I think, these sulphides are conductors to a degree not before recognised—a circumstance which renders a comparison of their conducting power with that of other conductors necessary.

Indirectly it has appeared, that nascent hydrogen is able to decompose these sulphides at common temperatures, by combining directly with their sulphur, thus accomplishing at a low temperature that which would require a very high one, in case it (the hydrogen) were presented to the sulphide in its ordinary form.

In relation to the amalgamating processes used for the extraction of gold at our batteries, these results prove that zinc amalgam, in contact with acid solution, has precisely the same effect in decomposing the sulphides of gold, mercury, iron, &c., as sodium amalgam; like this amalgam, therefore, it keeps perfectly bright and mobile in presence of sulphides, or the products of their natural metamorphoses.

Whether or no such an amalgam could ever be profitably substituted for sodium amalgam in our gold batteries has yet to be determined. I am afraid that the continual addition of sulphuric acid to the water conveying the auriferous stuff to the plates, &c., which the use of this amalgam necessitates, would increase so much the cost of extraction as to render it unprofitable; still, as the water need only be very slightly acidified, it may be well to keep the fact thus arrived at in mind, when projecting intended improvements in the amalgamation of the gold from auriferous reefs.

In conclusion, I will only now remark, that the kind of phenomena just described appear to have some relation to the formation and decomposition of metalliferous lodes.

It is pretty certain, analogically considered,* that these sulphides should be able to form among themselves a series of voltaic pairs in presence of saline solutions, as they differ from each other in respect to their affinities for oxygen. Galena and copper pyrites, for instance, should form a voltaic pair, in which the galena would be the negative element; sulphide of silver and galena again should furnish another pair, in which the galena would have its function reversed, and so on for the rest, according to their relative proneness to change.

In a natural way, therefore, the contact of dissimilar sulphides generally should set up galvanic action and chemical decomposition. and by setting up this action, we might have a sulphide decomposed by saline solutions, which it would be able to resist if it stood alone; or, on the other hand, we might have an easily decomposable sulphide preserved by the association with it of one still more ready to decompose.

* Since determined to be the case.

Since the results just detailed were arrived at, I have been referred by Dr. Hecfor to a paper by Mr. Robert Hunt, entitled, "Researches on the Influence of Magnetism and Voltaic Electricity on Crystallisation and Conditions of Matter," given in "Memoirs of Geological Survey of Great Britain," vol. i.

The subject of that paper is similar in part to this under consideration, but I do not see that the author has anticipated any portion of the results stated here; he certainly does not demonstrate the actual and continuous production of electricity by the contact of sulphides with positive bodies in saline solutions; nor does he show that copper pyrites conducts electricity, the water-line being, as you will observe by reference to his diagram 14, page 457, above the point of contact between the pyrites and the battery, so that the change or decomposition of the ore need not involve the necessity of conducting power in the pyrites, as in the case of that connected with the positive end of the battery, the conducting power necessary for this decomposition might well have progressed around, from this point or line of contact by the liberation of copper; while, in case of the other piece of pyrites, all the conducting power necessary for the production of the phenomena described may, with propriety, be referred to the wire bound around it.

I would also state, that in repeating this experiment of Mr. Hunt's I find that, different to his own observations as stated, both the pieces of pyrites are chemically affected, while it is not that in contact with the copper of the battery which displays such marked iridescence, but that communicating with the zinc; and it passes into this state, not by an oxidation process, but by a desulphurising one, brought about by the liberation of hydrogen upon its surfaces; this gas, when freshly liberated, having a desulphurising effect upon sulphides generally, as I have clearly shown above.

PRELIMINARY NOTICE ON THE AMIDO-DERIVATIVES OF ORCIN.

By JOHN STENHOUSE, LL.D., F.R.S.

In a paper I published on March 1st, 1871,* I mentioned that I had made some experiments on the action of reducing agents on trinitro-orcinic acid and trinitro-resorcinic acid, but as Dr. Schreder has recently announced† that trinitro-resorcinic acid is identical with oxypticric or styptic acid, and has investigated the amido-derivatives of it, I have not pursued my investigations farther in that direction, but have confined them to trinitro-orcinic acid.

Triamido-orcin, $C_7H_5(NH_2)_3O_2$.—When trinitro-orcinic acid is treated with reducing agents the NO_2 is replaced by amidogen, giving rise to amido-compounds. For the production of the triamido-orcin I find sodium amalgam to be the best reagent; as when nitro-orcin is agitated with water and sodium amalgam it rapidly becomes brown and ultimately colourless, giving rise to the triamido-orcin. The same substance is formed when trinitro-orcin is boiled with tin and hydrochloric acid, or with zinc and dilute hydrochloric acid. Intermediate amido-compounds appear to be formed, but I have not yet succeeded in isolating them.

Amido-diimido-orcin, $C_7H_5(NH_2)(NH)_2O_2$.—This substance is formed by the oxidation of triamido-orcin. When the colourless alkaline solution of triamido-orcin, obtained by treating nitro-orcin with sodium amalgam in the way already mentioned, is exposed to the air, it rapidly absorbs oxygen and acquires a magnificent blue colour, due to the formation of amido-diimido-orcin. The addition of an excess of sulphuric acid to this solution precipitates the

* *Proc. Roy. Soc.*, vol. xix., p. 410. Preliminary notice, *CHEMICAL NEWS*, vol. xxii., p. 98.

† *Ann. Chem. Pharm.*, vol. clviii., p. 244.

amido-diimido-orsin sulphate in dark purple brilliant scales, which can be obtained of great beauty by re-crystallisation from water, in which they are but slightly soluble. The addition of an acid renders them still more insoluble. By substituting hydrochloric acid for sulphuric acid in precipitating the blue solution the *amido-diimido-orsin hydrochlorate* is obtained in thin silky needles of a dark brown colour, which are much more soluble in water than the corresponding sulphate. The *nitrate* forms purple scales much resembling the sulphate, but more soluble, and is readily decomposed by excess of nitric acid. The *oxalate* is but slightly soluble, and crystallises in purple scales. The *picrate* forms iridescent green needles and plates, which are but slightly soluble. The *acetate* is much more soluble. The base itself, *amido-diimido-orsin*, can be obtained by treating the hydrochlorate with ammonia, or by exactly neutralising the blue alkaline solution before mentioned with hydrochloric acid, when the base separates in opaque needles having a green iridescent lustre. The base is but slightly soluble in dilute ammonia, and almost insoluble in water, but it dissolves readily in solution of sodic hydrate, with a fine deep blue colour, which gradually disappears on boiling, ammonia being evolved at the same time.

Nitric acid acts readily upon amido-diimido-orsin, forming an acid which gives crystalline salts the nature of which I have not yet determined.

A NEW METHOD FOR THE

DETERMINATION OF AVAILABLE CHLORINE IN "BLEACHING POWDER."

By J. B. F. HERRESHOFF,

Assistant in Brown University Laboratory, Providence, R.I.

HAVING had occasion to estimate the available chlorine in several samples of bleaching powder, and finding the methods now in general use inconvenient, and, unless executed with the utmost care, liable to much inaccuracy, I have of late devised a method which for accuracy, ease of execution, convenience, and economy of time, surpasses those in present use.

It is based upon the fact that when "bleaching powder" is made to act on an excess of stannous chloride in strongly acid solution, stannic chloride is formed at the expense of all available chlorine in the former. The reaction is represented by the following:—

Any excess of stannous chloride now remaining in solution is estimated by means of a standard solution of potassic dichromate, and, deducted from the former amount used, gives the weight of stannous chloride changed into stannic chloride by the "bleaching powder" used. The following represents the reaction:—

The process is conducted in the following manner:—

Weigh accurately 13.8738 grms. of pure potassic dichromate, dissolve in water, and dilute the solution to one litre. Each cubic centimetre of this solution has oxidising power equivalent to 0.01 milligram. of chlorine.

Weigh about 30 grms. of stannous chloride and dissolve in water, to which chlorhydric acid is freely added, and dilute the solution to one litre.

Fill two burettes with these solutions, run off about 10 c.c. of the stannous solution, dilute somewhat with water, and add about 5 c.c. of chlorhydric acid and a few drops of solution of starch, and potassic iodide. Now run in the solution of potassic dichromate, until a last drop gives to the solution a blue colour.

If it requires 20 c.c. of the standard dichromate solution, then 1 c.c. of the stannous solution will equal 2 c.c. of the former, and also 0.02 milligram. of chlorine.

Again, supposing the tin solution to be of the above strength, measure off 20 c.c. of the now standardised tin solution, dilute with water, as before, and add 1 gram. of the "bleaching powder" in question, well triturated with water, and then 10 or 12 c.c. of chlorhydric acid.

The reaction is energetic and complete, and, if sufficient amount of chlorhydric is introduced, the solution will become perfectly clear.

Add a few drops of solution of starch and potassic iodide, and then run in the potassic dichromate solution until the deep blue colour of iodide of starch remains permanent. Supposing 10 c.c. are required, then 10 c.c. + 2 c.c. = 5 c.c.; 20 c.c. - 5 c.c. = 15 c.c. As 1 c.c. of the stannous solution equals 0.02 Cl and 15 c.c. are required for 1 gram. of the "bleaching powder," then $15 \times 0.02 \text{ Cl} = 0.30 \text{ Cl}$, or 30 per cent.

Penot's arsenic method, the one now in general use, has disadvantages.

Arsenious acid is with difficulty purified, and there is no convenient method by which to test its purity.

The standard solution of sodic arsenite is tedious to prepare, from the fact that it requires a long time for complete solution of the required amount of arsenic in sodic carbonate solution.

This solution will not keep with certainty for any length of time unchanged, and is newly standardised only with difficulty, which arises from the fact that trouble is experienced in preparing perfectly pure iodine, caused mainly by its property of retaining moisture, and its volatility. This latter property is a source of much injury to the balance on which it is weighed, unless conducted in a closed vessel.

If the solution of iodine be of the correct standard no trouble is experienced in any further standardising the arsenious solution, provided the iodine solution be run into the latter, in which starch and an excess of sodic carbonate is present.

One great advantage in favour of the new method is that the standard potassic dichromate solution will remain for any length of time unchanged, and although the tin solution undergoes change, yet it is a matter of only a few moments to accurately re-standardise it by means of the dichromate solution.

The correctness of the results obtained by this method will be seen to depend upon the purity of potassic dichromate—a substance, though not always to be found of perfect purity, yet the impurities, which consist mainly of potassic sulphate, are so small as not to materially affect the final results.

This method gives accurately corresponding results. In four analyses made on a sample of "bleaching powder," the following results were obtained:—

	Cl.
1	26.42 per cent.
2	26.50 " "
3	26.56 " "
4	26.48 " "

—American Chemist.

ON THE

ACTION OF SULPHUROUS ACID ON METALS.

By P. SCHWEITZER, Ph.D.

Zinc and Sulphurous Acid.—If we dissolve metallic zinc by means of a mineral acid, and add a few drops of a solution of sulphurous acid, we observe, according to the strength of the sulphurous and hydrochloric acid per cent, a more or less rapid separation of sulphur and development of the odour of sulphuretted hydrogen gas. This is a reaction we resort to daily in our laboratories for the detection of sulphurous acid in hydrochloric, acetic, and other acids, and is so delicate a test for the presence of

this impurity, that the minutest traces of it may be discovered in this way without difficulty.

The reaction according to which this decomposition takes place is exceedingly complicated, and we look in vain to any of our text-books for information. Many false statements, too, will be encountered on the subject, which only a close study will reveal as such. In the following will be found the results of some experiments, undertaken with a view of settling this question :—

A strong solution of sulphurous acid was prepared, so as to be perfectly free from sulphuric acid, sulphuretted hydrogen gas, free sulphur, and oxygen, which, by the way, requires a great deal of care. In this acid, care being taken to exclude all atmospheric air, pure zinc was dissolved. No generation of gas could be observed, and the fluid, after deepening gradually in colour so as to become at last quite brown, like old sulphide of ammonium, commenced to separate sulphur, regaining its original colourless state after some time.*

While brown, and before sulphur had commenced to separate, part of the fluid was saturated with caustic potassa and tested for sulphur (as sulphide of potassium with nitroprusside of sodium), which was proved to be absent. After repeatedly shaking the fluid, which had become milky from separated sulphur, the solution itself being quite colourless, and allowing it to stand for several hours, a small amount of it was taken and tested in several ways. It contained still an excess of sulphurous acid, which, I may mention here, does not disappear even after standing for several weeks with metallic zinc, owing to the zinc becoming covered with a coating of sulphide of zinc, a trifling amount of which is always formed in this operation; part of it may be seen floating about in the liquid. Upon acidulating a part of the solution in question with hydrochloric acid and heating, sulphur separated in large quantities and of a yellow colour, while sulphurous acid was given off; another portion was acidulated with the same acid and left standing; in a few minutes sulphur separated, increasing in quantity while standing, and sulphurous acid being given off again. This established the presence of hyposulphurous acid, as no other known acid of sulphur is decomposed in the cold by a mineral acid into sulphur and sulphurous acid. Another portion of the fluid was then taken, diluted with water, acidulated with hydrochloric acid, and chloride of barium added. No precipitate whatever formed, proving the absence of sulphuric acid. This test has to be done quite rapidly, as after a few seconds sulphur begins to be separated, recognisable when in small quantity by the peculiar opalescent appearance it presents. A third portion of the fluid was acidulated with hydrochloric acid, boiled so as to decompose all polysulphur acids, which in the case of hyposulphurous acid cannot be accomplished in less time than two or three weeks. As the precipitated sulphur does not settle very quickly, the fluid was shaken with a small piece of bright metallic copper which rendered it clear almost immediately, so that it could be filtered and tested for sulphuric acid. A heavy precipitate was obtained with chloride of barium, proving the presence of this acid in large quantity and beyond doubt. This sulphuric acid, though not present in the original fluid, was produced therefore by the decomposition of a sulphur acid, and judging from the synthesis of these acids, this must have been trithionic acid.

* The few bubbles of gas escaping at the beginning are very probably carbonic acid. Zinc, like many other metals, oxidises in moist air, becoming thereby converted into basic carbonate. A stick of zinc, which had been cleaned beforehand with a file, so as to present a pure metallic surface, did not show the phenomenon of generating gas. Ordinary granulated zinc (which is always coated with a whitish oxycarbonate) shaken with water imparts to it an alkaline reaction, on account of the carbonate dissolving to a perceptible extent, and which may be easily tested with solution of cochineal. The amount of carbonic acid which all metals absorb, when exposed to the oxidising influence of moist air, is accounted for by the fact that it dissolves to

We have therefore present in the fluid, after aging with sulphurous acid on metallic zinc, SO_2 , S_2O_2 , S_3O_5 , S, ZnO, ZnS, a trace. I may mention here that a solution of hyposulphite of soda treated with sulphurous acid turns, especially upon heating, first yellow, then brown, sulphur separates, and trithionic acid is formed. The change of colour in the original experiments therefore indicates the point when trithionic acid is beginning to be formed. The reaction may be represented in the following way :—

The result being $\text{ZnO} \cdot \text{SO}_2$; $\text{ZnO} \cdot \text{S}_2\text{O}_2$; $\text{ZnO} \cdot \text{S}_3\text{O}_5$; besides sulphur, sulphide of zinc, and the undissolved metal. As regards the reaction under 3, I am perfectly aware that sulphur under ordinary conditions does unite with sulphurous acid, but if separated in the fluids containing it, its more active state may very likely favour such combination; the reaction under 4 is a fact, as it is a method for the preparation of S_3O_5 .

This fluid does not contain tetra- or penta-thionic acid, for on saturating it with caustic potassa and dissolving by an excess of alkali the first precipitated oxide of zinc, no sulphur separated to form sulphide of potassium on boiling. Both of these acids are decomposed, by boiling with alkalis, into sulphur and trithionic acid; this latter being decomposed in its turn again, but very much slower, into sulphurous and hyposulphurous acids.

Upon treating now sulphurous acid with metallic zinc in the presence of hydrochloric acid, we obtain a milky liquid, and the odour of sulphuretted hydrogen becomes more or less perceptible. The reaction here is more rapid and complicated. Zinc and hydrochloric acid generate hydrogen, as is well known, and the question may arise whether the hydrogen, being in the nascent state, will directly reduce sulphurous acid to water and sulphuretted hydrogen gas. Many metals decompose water, oxide of the metal being formed, while hydrogen is set free. On filling a little flask with sulphurous acid solution, inverting it and letting its mouth dip under sulphurous acid, contained in a porcelain dish, and introducing into the flask a piece of sodium, a vivid separation of hydrogen took place, while the sulphurous acid remained clear, and no trace of hydrosulphuric acid could be detected in the escaping gas. The same was observed when a piece of aluminium was substituted, in which case the fluid had to be heated to accelerate decomposition. The nascent hydrogen here was therefore without action upon the sulphurous acid, and it is not likely that, in the case of zinc and hydrochloric acid, the hydrogen should reduce sulphurous acid to water and sulphuretted hydrogen gas.

However, another experiment was tried, the result of which presents a still stronger reason for not considering hydrogen the reducing agent of sulphurous acid. In treating sulphurous acid with zinc and hydrochloric acid in the cold, until the reaction ceased, freeing the sulphur from the liquid in the way indicated, and adding to it more hydrochloric acid, and heating, a precipitate of sulphur was obtained, indicative of the presence of a polysulphur acid; but as no sulphuric acid could be found in the fluid, this must have been hyposulphurous acid. In order to succeed in this experiment much sulphurous and little hydrochloric acid must be taken; the separated sulphur there being also yellow. As therefore nascent hydrogen was without action upon sulphurous acid, but hyposulphurous acid and sulphur were separated, the probability is that sulphuretted hydrogen gas is formed by the direct combination of sulphur with hydrogen. In the moment of separation of both hydrogen as well as sulphur, we obtain all hydrogen and all sulphur as sulphuretted

a much larger extent in moist air than would correspond to 1:25 of a per cent, and that it very likely exists in this solution as carbonic acid and not as anhydride.

hydrogen; so in the case of treating sulphide of sodium with an acid.

But even one of these two elements, while in the nascent state, will combine with the other. We know that nascent hydrogen will combine directly with phosphorus, forming phosphuretted hydrogen; and, though sulphur, presenting so many strange and peculiar anomalies in its different states, may not unite as flowers of sulphur with hydrogen, it is very likely that sulphur, just separated from the decomposing hyposulphurous acid, will form sulphuretted gas, with nascent hydrogen. The sulphur certainly must have retained in this case some active principle, as it will directly combine upon shaking with metallic copper, and, as we will see hereafter, readily with metallic cadmium. Besides, sulphuretted hydrogen gas is only perceived in this reaction after sulphur has commenced to separate.

Cadmium and Sulphurous Acid.—In treating a piece of metallic cadmium, which had been rolled out to a very thin and long strip, with the same sulphurous acid, the reaction took place in a similar way as that with zinc. The fluid turned first yellow, but still remained clear, which required, however, a much longer time than with zinc, then darkened, separated a little white sulphur, and precipitated finally a large amount of sulphide of cadmium. This is insoluble in weak sulphurous acid, and therefore precipitated, while sulphide of zinc, being soluble, is consequently prevented from forming. We have a clear case here of separating sulphur combining directly with a metal. But this separating sulphur seems to have even the power of depriving salts like sulphide or hyposulphite of cadmium of its metal, forming thereby sulphide of cadmium and sulphuric acid. For while in the liquid resulting from the action of sulphurous acid upon cadmium, and which has been in contact with the metal for only three or four hours, no sulphuric acid can be detected before boiling, its quantity will be perceptible after standing in contact three or four days, and will increase by standing several weeks. This sulphuric acid derives its origin from the oxidation of the sulphurous acid by the oxygen of the metallic oxide, which is decomposed by the separating sulphur. The experiment can be easily made by adding a solution of either nitrate or sulphate of cadmium to hyposulphite of soda. Upon boiling, a slight opalescence only will be observed, as cadmium salts are generally acid, but no precipitate of either sulphur or sulphide of cadmium. Upon adding, however, a little hydrochloric acid, a heavy precipitate of sulphide of cadmium will be obtained immediately. The sulphur, therefore, from the decomposition of the hyposulphurous acid, was decidedly active.

The original fluid treated in the same way, viz., boiling with a little hydrochloric acid, immediately gave a precipitate of sulphide of cadmium. Before, however, any marked precipitate of CdS was observed, and after the fluid had remained in contact with the cadmium for about four hours, no sulphuric acid was found to be present, as has been already mentioned. Upon acidulating and boiling this solution, filtering out the separated sulphur, and testing the filtrate, much sulphuric acid was found, originating, as in the case of zinc, from the decomposition of S_3O_5 . The total reaction may be thus expressed:—

It is hardly necessary to say that the sulphuric acid will combine with oxide of cadmium, liberating either SO_2 or S_2O_2 . The fluid, after a sufficient length of time,

will therefore contain $\text{CdO} \cdot \text{SO}_3$; $\text{CdO} \cdot \text{SO}_2$; $\text{CdO} \cdot \text{S}_2\text{O}_3$; $\text{CdO} \cdot \text{S}_3\text{O}_5$; CdS; and the undissolved metal. All sulphur will have disappeared, and entered into combination with cadmium, so that a portion of the fluid, turbid and yellow from suspended sulphide of cadmium, will become clear upon acidulating with hydrochloric acid; no odour of sulphuretted hydrogen will make its appearance, as it is decomposed by the sulphurous acid. After filtering and washing, the precipitate, may, however, be readily recognised as CdS.

Nickel and Sulphurous Acid.—Nickel in form of the well-known cubes was treated with sulphurous acid in a bottle; the action proceeded similarly to that of the two former metals, but was very much slower even than that of cadmium. After several hours a darkening and green colouration of the fluid occurred, but a day elapsed before a separation of sulphur took place, and then only small specks of it were seen floating about. In this stage of the operation the fluid contained $\text{NiO} \cdot \text{SO}_2$; $\text{NiO} \cdot \text{S}_2\text{O}_2$; some sulphur, but no S_3O_5 or SO_3 . After several weeks' standing all sulphur had disappeared and combined with nickel as NiS, which in this case was certainly formed directly from the metal, as it presented the appearance of a black, heavy, scaly mass; this mass amounted to a considerable quantity, much more than could have formed from the little precipitated sulphur, and as much sulphuric acid was then to be found in the solution, we must conclude that either hyposulphite of nickel is not decomposed by sulphurous acid like the cadmium or zinc salt, but, under the influence and in contact with the metal and sulphurous acid, is converted into sulphuric acid, separating thereby sulphur, which combines with the nickel, thus:—

or we have to admit a secondary reaction of the sulphurous acid upon the metallic nickel, thus:—

I should decidedly favour the former view, which does not appear to be so very strange, if we remember that sulphurous and hyposulphurous acids are decomposed differently when combined with different oxides. I only recall the preparation of thithionic acid either from bisulphite of potassa with flowers of sulphur, or from hyposulphite of potassa by sulphurous acid. We do not get trithionic acid if we take in these cases soda instead of potassa salts.

However, we have in the fluid, after allowing the reaction to proceed for a considerable length of time, $\text{NiO} \cdot \text{SO}_3$; $\text{NiO} \cdot \text{SO}_2$; $\text{NiO} \cdot \text{S}_2\text{O}_2$; NiS.

Aluminium and Magnesium with Sulphurous Acid.—These two metals dissolve readily, the first in cold, the second in hot sulphurous acid. No sulphur is separated in the fluid, and no sulphuretted hydrogen gas is observed, as has been already mentioned. But upon analysing the clear solution, we find in both cases SO_2 ; SO_3 ; S_3O_5 ; S_2O_2 .

The presence of SO_3 and S_3O_5 , and the non-appearance of S, forces us to admit two or three reactions taking place simultaneously and independently of each other. The first, the solution of the metal by decomposing water, liberating hydrogen, and dissolving as oxide in the sulphurous acid; the second, the action of sulphurous acid upon the metal by forming a sulphide and hyposulphite; and the third, by forming a sulphate, hyposulphite, and trithionate.

- (1). $\text{Mg} + \text{HO} + \text{SO}_2 = \text{MgO} \cdot \text{SO}_2 + \text{H}$.
- (2). $2\text{Mg} + 3\text{SO}_2 = \text{MgO} \cdot \text{SO}_2 + \text{MgO} \cdot \text{S}_2\text{O}_2$.
- (3). $4\text{Mg} + 8\text{SO}_2 = \text{MgO} \cdot \text{SO}_3 + \text{MgO} \cdot \text{S}_3\text{O}_5 + 2(\text{MgO} \cdot \text{S}_2\text{O}_2)$.

These reactions seem to take place according to concentration, and depending in general upon conditions, which a future and closer study may reveal, and in the investigation of which, I hope, other chemists will participate.—*American Chemist*.

ON COLOURS FROM COAL-TAR.*

By HARRY N. DRAPER, F.G.S.

A FEW evenings since, when I was thinking how I might best place before you this subject of Colours from Coal-Tar in an instructive, and at the same time, if possible, an interesting manner, I chanced, in a very charming book, upon a passage which, with your permission, I will read to you.

"Yesterday forenoon, writes a friend, I went to the South Kensington Museum. It is really an absurd collection—a great deal of valuable material, and a great deal of perfect rubbish. The analyses are even worse than I was led to suppose. There is an *analysis of a man*. First a man contains so much albumen, and there is the albumen; so much phosphate of lime, fat, hæmatin, fibrine, salt, &c., &c.; then in the next case, so much carbon, so much phosphorus, a bottle with sticks of phosphorus, so much potassium; and there is a bottle with potassium, calcium, &c. They have not bottles of oxygen, hydrogen, and chlorine, but they have cubical pieces of wood on which is written, 'The quantity of oxygen in the human body would occupy the space of 170 cubes of the size of this.' What earthly good can this do any one?"—BROWN, *Horæ Subsecivæ*.

Now, when I tell you that, did I not stand in such close proximity to the admirable museum of this Society, and in awe of the unfavourable opinion of some friends of mine whom I see here, and whose opinion I respect, I should be much disposed to say "that, very little good indeed," you will understand that it is not without diffidence that I ask your attention to the somewhat formidable array of specimens which you see upon the table, or to the diagrams which hang against the wall. It is not that I have large sympathies with those, who, thinking the best part of a scientific lecture to be the experimental one, are ever on the alert for brilliant coruscations of light, and for explosions, but that I realise most fully the great difficulty of conveying anything like an accurate idea of complex chemical changes, with the opportunities and within the limits of a single lecture; and when we have, too, in the same hour, to occupy ourselves with the practical results of an important industry like this. However, as I have introduced the diagrams to your notice, it is but fair that I should be their apologist; and while, I think, I may say that they need not be a cause of uneasiness to us, I hope that when (as is but too probable) I come to use hard words, they will be a positive help, and give us some notion of what the hard words mean. And, as regards the specimens, I think when I say that each of them represents a fact, and often a very beautiful fact in chemistry, that each one of them has its own peculiar application in the arts or manufactures, and that they are, without exception, products of that wonderful fossil flora which we call Coal, you may be disposed to view them indulgently. I shall hope, too, to give them new interest in your eyes as we proceed; and it will be well if, at the outset, we get a clear idea of the object before us. We propose to trace the *useful*, as represented by this black, unsightly coal, in its progress towards the *beautiful*, as exemplified by the brilliant dyes with which we have been familiar during the past fourteen years. The mind, even when accustomed to chemical changes, and trained by experience to expect what would otherwise be startling results, does not easily grasp the conception that the millions of tons of coal which, in these islands, await the hands of the miner, represent a vast magazine, not only of light and heat, but of colour-giving substances, which vie in splendour with the tints of the most gorgeous exotics or the varied plumage of tropical birds.

The connection of colour with light is inseparable. We cannot imagine its independent existence. It is not

only when, as you have seen in some of the earlier lectures of this course, a ray of light is intercepted by a prism, that its velocity is altered, and that magnificent spectrum whose tints never weary us extends itself upon the screen; but nearly all bodies in nature split up white light, and in effect these differ only from prisms in that they absorb some rays and reflect others. That this is so we know; but though we may scarcely adopt the fanciful hypothesis of Darwin, whose "Ethereal powers"

"Cling round the ærial bow, with prisms bright,
And, pleased, untwist the sevenfold threads of light;
Eve's silken couch with gorgeous tints adorn,
And fire the arrowy throne of rising morn,"

we really know little more than we might thus express, and cannot predict, either from the shape, physical condition, or chemical constitution of a body, whether it shall appear to our eyes red, yellow, or blue. But grant white light and anything which will absorb a part of it, and you have colour. But does light, upon which so marked a change is effected when this partial absorption takes place, itself effect no change when it is, not partially but wholly absorbed by the bodies upon which it falls? All nature gives an affirmative reply. The snow-drop will flourish in the most secluded corner of the garden, and the wood-sorrel, we know, puts forth its pale blossoms in the shadiest dell; but it is in the full blaze of the tropical sunlight that cactus and aloë assume their vivid tints and the orchis takes its rainbow hues. Shall we, then, allow imagination too much rein if we think that centuries ago, when that which is now a coal-field was a waving forest, the light drunk in by every leaf did something more than clothe the copse in sombre green. May we not suppose that just as a logwood tree or an indigo plant of to-day returns in colouring matter the work done by the light it absorbs, these dark tracts of pines no less stored up their colour-giving substances but withheld them for a future age. And if we turn from the domain of fancy to that of fact, we see, as has been well pointed out by Hofmann, how much the practical science of to-day tends to turn to the vast storehouses of raw material which the mineral kingdom affords, and to form from inorganic bodies the most rare and costly products of organic life. Already, as he says, we have found the potash salts, which were hitherto obtained only from plants, in that great magazine of potash, the ocean; and paraffin and allied fatty bodies obtained from coal have already supplanted, to a very large extent, the fats and oils for which we were accustomed to look to animal and vegetable sources alone. So, in the same way, we have now some other things which, as flavours and perfumes, appeal to our senses of taste and smell, derived from mineral sources. It is not, then, after all, so very strange that we should seek and find *colour in coal*.

"Coal and Iron," it has been well said, "are kings of the earth;" and as we traverse to-day the desert of hard names and abstract fact which separates coal-tar from colour—a desert by the way in which there are a few pleasant oases—we shall do well to remember how much wealth from this source alone lies stored up in the coal-fields of Great Britain; and, perhaps, there are few cases we could select in which the contrast between the value of two substances is greater than it is between coal-tar and say, for example, purple dye; the first a fit type, if not of complete uselessness, at least of offensiveness; and the last so prized that a pound of wool dyed with the Tyrian purple, which, as we know, was obtained from a shell fish—the *murex*—sold at the time when Augustus reigned in Rome for a sum equivalent to £30 of our money. As I have mentioned this, it is, perhaps, but fair to say, that the purple of Tyre had an advantage which, in some degrees, compensated for its enormous price. We read that, when the Greeks sacked the treasury of Darius, they found a quantity of cloth dyed with this murex purple, which had retained all its brilliancy of colour after the lapse of 200 years. It was, therefore, essentially what ladies call a "fast" colour. It may not be out of place

* A Lecture delivered before the Royal Dublin Society.

to note, that nearly all the dyes with which we are familiar are of comparatively recent introduction. We never hear of woad now, but this favourite dye of our barbaric ancestors was only replaced by indigo in the reign of Elizabeth. And now, in our own day, indigo is being slowly but surely supplanted by the dyes which form a part of the wonderful series of "Colours from Coal-Tar."

And now we will endeavour, if you please, to follow the progress of this industry. All who hear me know, that in the manufacture of gas, coal is distilled in large retorts, made either of fire-clay or iron, from each of which a vertical tube rises. A number of these retorts are arranged together in a furnace; the retorts are made red-hot, and distillation at once commences.

Both the gas and the oily products of the coal pass up a vertical pipe, and (as this bends on itself) down again into what is called the "hydraulic main." Here all which is not gas condenses, and as the condensed liquid accumulates, it flows into a tank prepared for it. Coke alone remains in the retort. The condensed liquid is *coal-tar*—the body which interests us to-day. Now, this coal tar is, by distillation at a lower temperature, itself separable into two bodies—*pitch* and *tar oil*. The pitch is, as we know, used for the formation of the artificial asphalt, employed for footways, and in the manufacture of coarse black paints or varnishes. In this and other ways all the pitch which it was worth while to make found an outlet; but, because there was almost no other use for the tar oil than "creosoting" timber, it was almost without value. A glance at the diagram which we have here will show us that coal-tar oil is by no means a simple body. Hofmann, indeed, very properly speaks of it as "one of the most wonderful productions in the whole range of modern chemistry." We must not forget that not one of all these substances tabulated here exists *as such* in the coal itself. Indeed, if we were not aware what remarkable changes the simple application of heat is capable of making in most bodies, we should not be prepared for such a splitting up of what, at first sight, seems a very simple body indeed, into all these compounds. This action of heat sometimes shows itself in a very remarkable way. Here is a body: it is a compound of cyanogen and sulphur; and you see, that, as we have it here, it consists of small white lumps of a loosely-aggregated powder. Now, if I apply heat to this body, it changes its form in a very remarkable manner; and, having seen this change of form, you will readily understand that its chemical properties and chemical composition have also undergone complete change. So it is with coal: the mere application of heat, to a certain degree, not only changes its form, but resolves it into all these bodies, each of which has some important chemical difference from its neighbour.

Perhaps, if we only knew how to go to work, we should discover that there are very few things in nature from which we could not obtain colour. But the tendency of these component parts of coal-tar to form coloured compounds is very remarkable. I might show you this by more or less elaborate methods, with almost any one of them; but here is one of the simplest examples. I mix a few drops of this body, which, as we shall have more to say to it presently, I will not describe now. I mix it with the water in this jar, and then add a solution of a persalt of iron. You see we have a violet colouration at once developed. But there are *five* constituents of tar, in which the tendency to give colour is so very marked that all the interest of coal-tar, as a practicable source of colour, centres in them. These five bodies are benzol, toluol, phenol, naphthalin, and anthracen; and as it is from these alone that the coal dyes are obtained, we have arranged them here on a separate diagram, in which each is shown, with the principal colours derived from it. You will see, also, specimens of each of these bodies on the table, and will observe some characteristic points of difference, even in their appearance.

Now, in separating these substances from coal-tar oil,

advantage is taken, firstly, of differences of boiling point and, secondly, of the various behaviour of these bodies with acids and alkalies. Glancing at the diagram, we see, for instance, that *benzol* boils at 84°; *toluol* at 114°; and *phenol* at 188°; so that, if we subject a mixture of these three bodies to distillation, we shall obtain—first, the benzol; then, as the temperature increases, the toluol; and, finally, when the thermometer reaches 188°, the phenol.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Annual Meeting, April 18th, 1871.

E. W. BINNEY, F.R.S., F.G.S., President, in the Chair.

Dr. JOULE, F.R.S., drew attention to the remarkable atmospheric phenomenon which had been seen by several persons in Derbyshire and elsewhere, on the evening of Good Friday, April 7th, and stated that he had witnessed a similar appearance near Glasgow, on the day before it was observed in this neighbourhood. The perpendicular ray extended upwards from the sun to an altitude of 30°, and was very clearly defined. It was observed from half an hour before until after the sun had set. The phenomenon was also witnessed, at the same time, by Professor J. Thomson, who was sailing on the Firth of Clyde.

The following Report of the Council was read by one of the secretaries:—

The Council have the satisfaction to report that the past year has been one of steady progress for the Society. On the 31st of March, 1870, the general balance of the Treasurer's account was £268 1s. 2d., and on the 31st of March last it had increased to £287 19s. 1½d.

The number of ordinary members on the roll of the Society on the 1st of April, 1870, was 161, and 14 new members have been since elected. The losses during the year have been—Deaths, 1; resignations, 3; and defaulters 2. The number of the roll on the 1st of April instant was therefore 169.

In the last annual Report it was stated that in consequence of the rapid increase of the library of the Society it would be necessary to provide additional accommodation. This has since been done, a new bookcase having been fitted up in the Council room in place of a smaller one, which has been removed into the tea room.

The Council refer with pleasure to the fact that the principal result of the recent solar eclipse expedition is due to the energy, intelligence, and skill of a member of the Society, Mr. Alfred Brothers, F.R.A.S., whose beautiful photograph of a solar corona is now generally regarded as having settled the long disputed question as to the real nature of this remarkable phenomenon.

The printing of the fourth volume of the Society's third series of Memoirs has been completed, and a new volume has been commenced.

During the session now ending an important alteration has been made in the terms of admission of Sectional Associates, the annual subscription having been reduced from £1 to 10s., except for those Associates who wish to make use of the Society's library, who will still continue to pay a subscription of £1 per annum.

The librarian reports that he has not been able to send any books to be bound in the course of the past year. The Society continues to receive the publications of those societies to whom our own "Memoirs" and "Proceedings" are sent, but the recent war between France and Germany has to some extent interrupted the transmission of the works of many continental societies.

The following gentlemen were elected officers of the Society and members of the Council for the ensuing year:—

President—Edward William Binney, F.R.S., F.G.S.
Vice-Presidents—James Prescott Joule, D.C.L., LL.D., F.R.S., F.C.S., &c.; Edward Schunck, Ph.D., F.R.S., F.C.S.; Robert Angus Smith, Ph.D., F.R.S., F.C.S.; Rev. William Gaskell, M.A.

Secretaries—Henry Enfield Roscoe, B.A., Ph.D., F.R.S., F.C.S.; Joseph Baxendell, F.R.A.S.

Treasurer—Thomas Carrick.

Librarian—Charles Bailey.

Other Members of the Council—Peter Spence, F.C.S., M.S.A.; William Leeson Dickinson; Henry Wilde; Robert Dukinfield Darbishire, B.A., F.G.S.; Osborne Reynolds, M.A.; William Boyd Dawkins, M.A., F.R.S.

CORRESPONDENCE.

THE PHOSPHATE SEWAGE PROCESS.

To the Editor of the Chemical News.

SIR,—Some time since you were good enough to insert in the CHEMICAL NEWS a letter from myself, asking Dr. Voelcker a question regarding the analysis of the "dried sewage deposit" (prepared according to Dr. Forbes's "patent phosphate process for the utilisation of sewage,") which appeared in No. 589.

The deposit was found by Dr. Voelcker to contain 28.52 per cent of phosphoric acid; 29.95 per cent of alumina and oxide of iron, sufficient to combine with all the phosphoric acid present; also a quantity of lime, insufficient to combine with more than about half the phosphoric acid.

Being considerably interested in phosphatic manures, I was anxious to know how much of the phosphoric acid Dr. Voelcker would consider as being in combination with the alumina, and how much with the lime, for upon this agriculturalists and many manufacturers at present believe the value of the deposit as a manure to entirely depend, the more so because Dr. Voelcker, in his analysis, stated the phosphoric acid to be equal to a certain quantity of phosphate of lime, which, on first reading, may be taken to mean that he considers it to be really in combination with the lime, and not with the alumina and iron as one would suppose from the well known chemical affinity of the acid for these bases.

I looked forward to Dr. Voelcker's reply, in the hope of having my scruples set at rest; but not receiving one, I procured some native phosphate of alumina and made the following experiment. I dissolved the mineral in sulphuric acid, and to the clear saturated solution added milk of lime in slight excess. The precipitate was collected on a filter, well washed, and analysed. I found that the whole of the phosphoric acid which it contained was combined with alumina and a little oxide of iron, mere traces only being soluble in acetic acid, showing the almost complete absence of phosphate of lime.

Now, assuming that all the phosphoric acid present existed as the soluble phosphate of lime, the value of the deposit as a manure would not greatly exceed the value which Dr. Voelcker assigns to it, viz., £7 7s. per ton; but if (as I must infer from my experiment), nearly the whole of the phosphoric acid is combined with alumina and iron, of what value will such a manure be as a fertilising agent? If, indeed, phosphate of alumina be the excellent manure which Dr. Voelcker appears to consider it, from the value he attaches to this "sewage deposit," how is it that Messrs. Lawson and Son do not convert the native mineral phosphate directly into a manure by the ordinary method of treatment with acid, instead of doing so by the very roundabout plan known as Forbes's patent process?—I am, &c.,

SUPERPHOSPHATE.

Royal College of Chemistry, London,
June 20, 1871.

MISCELLANEOUS.

The Abbé Moigno.—As will be seen from our Chemical Notices from Foreign Sources, the Abbé Moigno has again resumed the publication of *Les Mondes*. Subscribers' names and subscriptions will be received at our office. The learned editor was unable to continue his duties during the disasters which attended and followed the late war. He has now, however, resumed them with renewed energy and with the determination to make the journal even more useful than before.

A New Brass.—The difficulty of uniting iron to brass is created by the unequal rate of expansion in the two metals, which destroys the unity when the temperature is changed. A new alloy of copper is announced, and the inventor claims that its expansion by heat is so similar to that of iron and steel, that the surfaces may be regarded, when joined, as permanently united, for all practical purposes. The formula (recently published in the *Journal of Applied Chemistry*) is as follows:—Tin, 3 parts; copper, 39½ parts; zinc, 7½ parts. Any of our readers who have occasion to join iron and brass, can easily try this new "metal," and we shall be glad to hear of the practical value of an idea of such high technical importance.—*Scientific American*.

London Institution.—The managers of the London Institution, in accordance with the recommendation of the annual meeting of proprietors, have resolved to afford opportunities during the ensuing season for the reading and discussion of communications on subjects of special interest in science, literature, commerce, and the arts, provided they receive such offers as will ensure an adequate succession of suitable papers. It is believed that this proposed extension of the use of the Lecture Theatre in Finsbury Circus will produce a series of attractive meetings similar in character to those of the Society of Arts, but representing more directly the business and thought of the city. The managers do not intend to restrict the reading and discussion of papers to the proprietors of the institution, or to limit the range of subjects otherwise than by the provisions of the charter, which preclude politics and theology.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, No. 1, January 2, 1871.

The only paper relating to chemistry and collateral sciences is on—

A Process for Purifying Fatty Substances.—A. Boillot.—The process alluded to is the treatment of the fat—be it suet or any other—with lime-water (*aqua calcis*), heat being applied at the same time. For 1 kilo. of the fatty substance, 2 litres of lime-water are taken. After cooling, the fatty substance is placed in a linen or flannel bag, and submitted to a gentle, but gradually-increased pressure. The fat left in the bag is next melted in hot water to which some sulphuric acid has been added, and after being cooled and well washed with cold water is ready for domestic use, since it appears from the context of the paper rather than this process is intended to be applied to render fatty substances, otherwise used for soap and candle making, fit for culinary use, the reader being reminded of the condition Paris was in when this paper was published.

No. 2, January 9, 1871.

Historical Account of the Scientific Researches on Gelatine.—E. Chevreul.—The third instalment of this very exhaustive and valuable monograph; not suited, however, for any useful abstraction.

Colza Oil.—A. Wurtz and E. Willm.—The authors state, that when into this oil a current of steam is passed having a temperature of about 120°, there is removed from the oil, which is not thereby to any extent saponified, an acid principle; and after a washing with a hot solution of carbonate of soda, the oil so purified, after washing, of course, with cold water, may be used for culinary purposes.

The other papers relating to the matters above named bear upon the same or similar subjects, and are rather to be considered as tentative suggestions brought out under peculiar circumstances, and therefore not of general value.

No. 3, January 16, 1871.

This number opens with a valuable essay on—

Dwelling-House Chimneys.—General Morin.

Composition of Milk, and on the Preparation of an Obsidian Milk.—Dr. Dubrunfaut.—The contents of this paper bear only upon the late exceptional condition of Paris, and the scarcity of milk there experienced.

Plan for Utilising the Sewage of Paris.—M. Durand-Claye.—Illustrated by a woodcut.

Nos. 4 and 5, January 23 and 30, 1871.

Do not contain any papers relating to chemistry and collateral sciences.

No. 6, February 6, 1871.

Discovery of Avic Acid in an Albatross.—E. Chevreul.—The eminent author relates at length how, on the 19th of January last, he accidentally made the discovery that the feathers of the well-known large bird called the albatross contain a volatile fatty acid, identical with that which the author has found in the suint of sheep's wool. No further particulars, nor any analysis, of the acid alluded to is here quoted, the author having simply relied on his sense of smell, thereby recognising the well-known odour of the fatty acid alluded to.

Preservation of Potatoes by the Aid of Sulphurous Acid Gas.—V. Labarre.—The author proposes to cause a current of sulphurous acid gas to be passed among the tubers alluded to, either while packed in casks or placed in cellars, since by the use of this gas the fermentation and decay of the potatoes is checked.

Nos. 7, 8, and 9, February 13, 20, and 27; and No. 10, March 6, 1871.

These numbers do not contain papers relating to chemistry and collateral sciences.

No. 11, March 13, 1871.

This number contains the following original paper relating to chemistry:—

Researches on Propylic Bromide and on Butylic Bromide.—I. Pierre and E. Puchot.—The authors describe, at length, the mode of preparation of propylic bromide, C_3H_7Br , by pouring into a long-necked flask 100 parts of pure propylic alcohol, and next, alternately, and by small quantities at the time, 15 parts of phosphorus and from 140 to 145 of bromine, care being taken to keep the phosphorus constantly in excess. After purification of the crude product, a clear, colourless, ethereal liquid is obtained, which boils at 72°, and has at 0° a sp. gr. of 1.349. By contact with moist air, this liquid gradually becomes somewhat coloured. Butylic bromide, C_4H_9Br , is prepared by a similar process to that just alluded to, the only difference being that 120 parts of pure butylic alcohol are taken. The rectified butylic bromide boils at 90.5°, and has at 0° a sp. gr. of 1.249; when freshly prepared, this liquid is colourless, but it soon becomes coloured by a partial decomposition.

No. 12, March 20, 1871.

Preparation of Two Organic Acids obtained by the Reaction of Alkalies upon Silk and Wool.—P. Champion.—*Sericic Acid.*—Raw silk, having been first purified by boiling alcohol, ether, and acetic acid, is treated with boiling baryta-water, whereby a portion of the substance is dissolved; the excess of baryta is removed by carbonic acid from the liquid kept at 80°. After filtration, the filtrate is treated with nitrate of lead, whereby an abundant precipitate is obtained, which, having been collected on a filter and thoroughly washed, is suspended in water and decomposed with sulphuretted hydrogen, the liquid yielding, after filtration and evaporation on a water-bath, an amorphous, slightly yellow-coloured, translucent, deliquescent mass, soluble in alcohol and acetic acid. The baryta salt of this substance, having the same physical properties, was, on analysis, found to yield results leading to the formula $C_{20}H_{29}N_3O_{14}Ba$. *Lanugic acid*, obtained from previously well purified wool by the same process, and yielding a body of similar physical properties, was, on analysis of the baryta salt, found to lead to the formula $C_{88}H_{120}N_{10}O_{40}Ba$.

No. 13, March 27, and Nos. 14, 15, and 16, April 3, 10, and 17, 1871.
Do not contain any papers relating to chemistry.

No. 17, April 24, 1871.

The only paper relating to chemistry in this number treats on the—**Saccharate of Chloride of Sodium.**—Dr. E. J. Maumené.—The author describes, at great length, a series of experiments made with the view to ascertain the precise constitution of the sugar contained in some well-defined large colourless prismatic ortho-rhombic crystals, consisting of 13.295 per cent of chloride of sodium, the rest being sugar, which latter the author's experiments prove to be pure cane sugar; so that thus the compound just alluded to is really a saccharate of chloride of sodium.

No. 18, May 1, 1871.

This number does not contain any papers relating to chemistry.

No. 19, May 8, 1871.

Contains only the following paper bearing on chemistry:—

New Blue Colouring Matter Derived from Eserine.—A. Petit.—Eserine (a very strong base) is carefully saturated with sulphuric acid, and next ammonia in excess is added; the liquid is then evaporated to dryness upon a water-bath, leaving a solid magnificently blue-coloured substance, soluble in alcohol and water, crystallising, and colouring silk blue without the aid of a mordant. The action of acids renders the colour beautifully violet. When eserine is directly treated with ammonia, without having been first saturated with sulphuric acid, there is obtained, on evaporation, a greenish coloured mass, less soluble than that alluded to, and turning wine-red when acted upon by acids. The composition, properties, and mode of formation of the blue pigment alluded to have not been ascertained as yet by the author, who is engaged in further experiments on this subject.

Nos. 20 and 21, May 15 and 29.

The Academy did not meet on May 22. These numbers do not contain any papers relating to chemistry.

Zeitschrift für Chemie von Deilstein, No. 6, 1871.

The only original memoir contained in this number is—

Thio-Aniline and Thio-Toluidine.—V. Merz and W. Weith.—The authors describe, at length, a series of experiments made by them on the action of sulphur upon aniline and toluidine, aided by heat, and best, also, assisted by the simultaneous action of litharge, which greatly accelerates the sulphurisation of the aniline and toluidine, and to some extent prevents the formation of resinous by-products. The result is the formation of thio-aniline, $C_6H_4N_2S$, a body difficultly soluble in both cold and hot water; but readily so in alcohol, ether, and best in hot benzol, from which it is deposited, on cooling, in crystalline state. Thio-aniline is devoid of smell, has a burning taste, exhibits a neutral reaction to test-paper, and fuses at 105° (when heated under water, it fuses even below 100°); by dry distillation, it at first gives off a very irritating vapour, next chiefly aniline and sulphuretted hydrogen, leaving a large quantity of carbonaceous residue. Thio-aniline behaves as a diamine, fixing 2 equivalents of acid without neutralising it; the salts are generally crystalline. The authors describe a series of these salts, among which the following:—Thio-aniline-chlorhydrate, $C_{12}H_{12}N_4S_2HCl + 2H_2O$.—Insoluble in ether, alcohol, and cold concentrated hydrochloric acid; readily soluble in water. Thio-aniline-platin-chloride, $C_{12}H_{12}N_4S_2HCl.PtCl_4$. Thio-aniline-sulphate, $C_{12}H_{12}N_4S_2H_2SO_4 + H_2O$.—Difficultly soluble in cold water; more readily so in hot water and very dilute sulphuric acid; almost insoluble in alcohol and ether; crystalline. Thio-aniline-oxalate, $C_{12}H_{12}N_4S_2H_2C_2O_4$.—Most of the salts of thio-aniline exhibit an acid reaction; even their very dilute solutions impart to fir-wood a beautiful orange colour; with chloride of iron, an intensely blue violet colouration is produced. Thio-aniline is, like the haloid aniline compounds, a very stable body; treated with chloracetyl, the benzol solution of thio-aniline yields thio-acetaniline—

This substance is readily soluble in boiling alcohol, but difficultly so in ether and water; it is a crystalline body which, instead of being prepared as just stated, is more readily obtained by boiling the thio base for several hours with concentrated glacial acetic acid, the only difference between these two preparations being the point of fusion, which, for the chloracetyl preparation, is 213.5°, for the other 215°. Thio-sulpho-carbanilide is obtained by the action of alcoholic solutions of sulphide of carbon and of thio-aniline upon each other. The authors next treat on the resinous products of the sulphurisation of aniline; the purified resinous matter, dried at 120°, yielded 20.87 per cent of sulphur. Thio-toluidine, $C_7H_7N_2S$, a crystalline substance, almost insoluble in water, very readily so in ether, and tolerably so in alcohol; devoid of taste and smell; reaction neutral; fuses at 103°. This base forms salts with acids, but they are decomposed by a large quantity of water; the salts exhibit a strongly acid reaction. Toluidine-chlorhydrate, $C_{14}H_{12}N_2S_2HCl$, a crystalline salt, yielding, with platinum-chloride, a double salt, $C_{14}H_{12}N_2S_2HCl + PtCl_4$. Thio-toluidine-sulphate, $C_{14}H_{12}N_2S_2H_2SO_4$, contains 28.66 per cent of sulphuric acid, is decomposed by boiling water, insoluble in alcohol, and soluble in very dilute sulphuric acid. The authors briefly mention a series of experiments made with the view of the sulphurisation of benzol, but none of these experiments led to the desired result. The passing of vapours of benzol over black sulphuret of antimony heated to redness caused the benzol to be converted into diphenyl.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 4, 1871.

This number contains the following original memoirs and papers relating to chemical and collateral sciences:—

Steam-Boiler Explosions.—Prof. Melsens.—The first instalment of a very important memoir on this highly interesting subject.

E. W. Prevost (Heidelberg).—Duplicates of the numbers have been forwarded to you.

THE CHEMICAL NEWS.

Vol. XXIII. No. 605.

SUGGESTIONS FOR THE IMPROVEMENT OF THE METHODS EMPLOYED IN QUALITATIVE ANALYSIS.

By A. H. ALLEN, F.C.S.

It is not supposed that the following remarks contain much that is new, or that experienced chemists would have any difficulty in avoiding error, but I am anxious to call the attention of teachers to the existence of the defects, and the means I would suggest for their removal.

When imparting instruction in qualitative analysis, I have frequently found that the pupils have a difficulty in ascertaining that the substance under investigation is a metallic oxide or hydrate. In my opinion, there are few works on qualitative analysis which give anything like sufficient prominence to these important classes of compounds. Ordinarily, the student is directed to search first for the metal and then for the "acid," and there is generally some short note or observation to the effect that "if no acid can be detected, the substance is probably an oxide or hydrate." I have always found it preferable to test for these classes of compounds before proceeding to the method for the detection of other salt radicles. It is a curious fact that in two recent works on qualitative analysis little or no notice is taken of the solubility of various compounds. In my opinion, the solubility is a most important aid in the analysis of both simple and complex substances, and the manuscript "tables of solubilities" used by my pupils have the solvents for all the important classes of salts, with the addition of the colour when this is peculiar and characteristic, and notes in certain cases.

When the metal is ascertained, and the solvent for the substance known, it is very easy to look at this table and learn from it whether the solubility and colour are in accordance with those of any oxide or hydrate of the metal detected. If not, the ordinary method is in no way lengthened; but should the properties agree it is much better to try a few tests to ascertain if the substance be really an oxide or hydrate, than to wade through a tedious method for the detection of salt radicles, and then get the same result in the end "by difference."

Again, a method for the analysis of simple salts ought to be applicable to any ordinary inorganic solid or liquid likely to occur in a laboratory in a single bottle. Thus, if many analytical systems be followed, potassium chromate can only be analysed by a method for mixtures, though it is essentially a "simple substance containing one base and one acid." Ferro- and ferricyanides are not of more frequent occurrence than the permanganates, yet few text-books give any hint of the properties of the latter salts, or contain any note of the abnormal reactions their presence would occasion. Sodium aluminate is, to all intents and purposes, a simple salt, and it is tolerably frequently met with, but if the student examine it by almost any of the ordinary text-books he will fail to ascertain its composition, and trying in vain for an "acid" will begin to think he has met with a soluble oxide or hydrate of aluminium. Sodium stannate, arsenite, and arseniate, are other instances of the same difficulty. Of course it may be said that the student is not supposed to work alone, and that these difficulties will be explained away as they arise; but why should the majority of text-books take no notice of them, or only refer to them in another part of the book instead of calling attention to a possible result in the place where the difficulty would occur.

For these reasons, I direct my pupils to detect the metal first, and then to refer to a table containing descriptions of the chief oxides, hydrates, and anomalous compounds of each metal, while at the same time he is warned that every mentioned property and reaction of the oxide, &c., must be realised before deciding that it is really that compound of the metal. The classes of salts most liable to be mistaken for oxides or hydrates are the sulphides and carbonates, and in some cases the phosphates, arseniates, and oxychlorides. Possibly, a few examples may make my meaning clearer.

(1.) The substance under examination is supposed to be simple, and the metal has been proved to be magnesium. The substance is white, and insoluble in water, but readily soluble in HCl. Instead of going through the whole method for the detection of salt radicles, and coming at last to the conclusion that the substance is MgO, the analyst looks at the table of oxides, &c., and finds the following particulars under the head "Magnesium."

"Magnesium."	{ Oxide, Mg"O. Hydrate, Mg"HO ₂ .	White, insoluble in water, soluble in HCl without sensible effervescence. Turns yellow when boiled with HgCl ₂ . Turns wet red litmus-paper blue. The hydrate gives off water at a red heat."
--------------	---	--

These few reactions are sufficient to distinguish the oxide or hydrate from any other compound of magnesium.

(2.) The substance is black, insoluble in water, soluble in HCl, and has been found to contain copper. Of course, an advanced student would immediately suspect that it was CuO, especially as Cu₂S and CuS are only dissolved by HCl with great difficulty. But the student with a limited knowledge and a short memory would probably wander through the whole acid method, while he might at once detect the nature of the substance by looking at such a table as I describe, where he would read—

"Copper."	{ Cuprous oxide, Cu ₂ O. Red. Cuprous hydrate. Yellow. Cupric oxide, Cu"O. Cupric hydrate, Cu"HO ₂ .	Soluble in HCl, without effervescence or smell of H ₂ S. Black. Soluble in HCl, without effervescence or smell of H ₂ S. Bluish. Turns to black CuO when boiled in water. Soluble in HCl, without effervescence or smell of H ₂ S."
-----------	---	--

One more instance will suffice. (3.) The substance is white, soluble in water, and has been found to contain barium. The Table says—

"Barium."	{ Barium oxide, Ba"O. Barium hydrate, Ba"HO ₂ . Barium dioxide, BaO ₂ .	White or grey. Soluble in water; solution alkaline to litmus, and gives brown Ag ₂ O with AgNO ₃ . Aqueous solution does not effervesce, or evolve H ₂ S with HCl. The hydrate gives off water when heated to redness with dry SiO ₂ . White. Insoluble in water; soluble in HCl. The solution bleaches and liberates I from KI."
-----------	---	--

This plan is not merely more speedy and accurate than that usually followed, but it familiarises the student with the properties of the various oxides, and gives them their

proper position of precedence. The method for detecting sulphides is not always clearly laid down, and I think might be improved.

Another fault that is common in works on qualitative analysis is the omission of any systematic means of detecting the salts of hydrogen. Considering how important and common are many of the compounds of this "metal," it should have a definite place in the analytical method. Sourness, and the property of reddening litmus-paper, are general properties of the salts of hydrogen, which should no more cause it to be slurred over than the sweet taste of lead compounds, the blue or green colour of salts of copper, or the tendency of silver compounds to blacken in the light, are reasons for the exclusion of these metals from the general method. Of course, hydrogen will be grouped with potassium, sodium, and ammonium, and the students must be taught to ascertain whether the original substance is an acid or anhydride. A few simple tests will generally decide this question, a table of the properties of the principal acids, anhydrides, and salt radicles being employed for the purpose.

In many handbooks there is to be found a direction somewhat to the following effect. "Before passing H_2S , if arsenic has been found in the preliminary examination, the solution must be boiled with sulphurous acid."

Now, this renders it necessary to make a "preliminary examination," which is not always convenient, especially with a liquid, and in the hands of beginners the dry test for arsenic is very liable to failure when applied to the sulphides of arsenic and the arseniates. Suppose sodium arseniate is under examination, this direction would make it necessary to examine the substance as a "mixture," while no difficulty will be met with if the following plan be employed. Omit the reduction with sulphurous acid, and, in all probability, the arsenic will not be thrown down by H_2S , and the analyst will find the metal to be sodium. The method for the detection of salt radicles will then readily reduce the question to the phosphate or arseniate, which, of course, are distinguished by silver nitrate. If H_2S does produce a precipitate, arsenic will be detected, and, on reference to the above-mentioned table of oxides and anomalous substances the analyst will learn that the brown Ag_3AsO_4 produced with silver nitrate indicates an arseniate, its incomplete volatility shows that it is not the hydrogen or ammonium salt (or arsenic pentoxide), and a reference to the table of solubilities will tell him that the only other arseniates soluble in water are those of potassium and sodium. The same plan would be preferable if arseniate of calcium or iron were under examination, the arseniate being mistaken for phosphate up to a certain point, and then readily distinguished from the latter.

I am engaged on a work on analysis in which the above suggestions are incorporated, and I shall be obliged to anyone who will assist me in reducing the chances of error for beginners in analysis.

ON THE ACTION OF HYDROBROMIC ACID ON CODEIA AND ITS DERIVATIVES.*

By C. R. A. WRIGHT, D.Sc.,
Lecturer on Chemistry in St. Mary's Hospital Medical School.

It has been shown in Part I. of this research† that the action of hydrobromic acid on codeia gives rise, without evolution of methyl bromide, first to bromocodide, and secondly to two other new bases termed respectively deoxycodide and bromotetracodeia, the latter of which, under the influence of hydrochloric acid, exchanges bromine for chlorine, yielding a corresponding chlorinated base, chlorotetracodeia; when, however, the action of

hydrobromic acid is prolonged, methyl bromide is evolved in some little quantity. By digesting codeia with three or four times its weight of 48 per cent acid for five or six hours on the water-bath, vapours were evolved which, condensed by the application of a freezing mixture to a colourless mobile liquid, the boiling-point of which was found to be 105° to 115° , and the vapour of which burnt with a yellow-edged flame, exploded violently with oxygen, forming carbonic and hydrobromic acids; it becomes, therefore, of interest to examine in detail the action of hydrobromic acid on each of the three bodies produced from codeia under its influence.

1. Action of Hydrobromic Acid on Bromotetracodeia.

When bromotetracodeia hydrobromate is heated in a sealed tube to 100° with four or five times its weight of 48 per cent hydrobromic acid for from six to ten hours, methyl bromide is found as a thin layer on the top of the tarry contents of the tube after cooling; by dissolving this tarry substance in water and fractionally precipitating the liquid by strong hydrobromic acid several times successively, nearly white amorphous flakes are ultimately obtained, resembling in all their physical and chemical properties the bromotetracodeia hydrobromate originally employed. After desiccation, first over SO_2H_2 , and finally at 100° , there were obtained numbers which correspond with those required for a base bearing the same relation to morphia that bromotetracodeia does to codeia; it is, therefore, provisionally named bromotetramorphia.*

Hence the action of hydrobromic acid on bromotetracodeia is

Carbonate of soda throws down from the solution of the hydrobromate a nearly white precipitate which rapidly oxidises, and appears identical in all its physical properties and chemical reactions with bromotetracodeia.

When crude bromotetramorphia hydrobromate is precipitated by carbonate of soda, and the precipitate (after filtration and washing) re-dissolved in hydrochloric acid and fractionally precipitated twice or thrice by strong hydrochloric acid, white flakes free from bromine are ultimately obtained; these are the hydrochlorate of the corresponding chlorinated base, which is therefore termed chlorotetramorphia. After drying at 100° , numbers were obtained which led to the formula $\text{C}_{60}\text{H}_{75}\text{ClN}_4\text{O}_{12} \cdot 4\text{HCl}$.

Converted into platinum-salt and dried at 100° :—

0.4235 grm. gave 0.0840 Pt = 19.83 per cent.

The formula $\text{C}_{68}\text{H}_{75}\text{ClN}_4\text{O}_{12} \cdot 4\text{HCl} \cdot 2\text{PtCl}_4$ requires 19.72 per cent.

When codeia is heated on the water-bath with three parts of 48 per cent hydrobromic acid for five hours, and the portion of the precipitate thrown down by carbonate of soda and insoluble in ether is dissolved in hydrochloric acid, and fractionally precipitated several times by excess of stronger acid, flakes are obtained which, on drying at 100° , yield numbers intermediate between those required for chlorotetracodeia and chlorotetramorphia, leading to the formula $\text{C}_{70}\text{H}_{79}\text{ClN}_4\text{O}_{12} \cdot 4\text{HCl}$.

Converted into platinum-salt, and dried at 100° :—

0.4830 grm. gave 0.0935 Pt = 19.36 per cent.

The formula $\text{C}_{70}\text{H}_{79}\text{ClN}_4\text{O}_{12} \cdot 4\text{HCl} \cdot 2\text{PtCl}_4$ requires 19.40 per cent.

Whether this is only a mixture of chlorotetracodeia and chlorotetramorphia hydrochlorates, or is one compound, is open to doubt; assuming that it is not a mixture, the name chloro-dicodide-dimorphia might be applied to the base. It appears *a priori* probable that the following double series of bases should be obtainable by successive methyl eliminations :—

* Read before the Royal Society, June 15, 1871.
† *Proc. Roy. Soc.*, vol. xxi., p. 317.

* All combustions given in this paper were made by lead chromate and oxygen; except where otherwise stated, chlorine and bromine were determined by boiling with silver nitrate and nitric acid.

Bromotetracodeia	$C_{72}H_{83}BrN_4O_{12}$
	$C_{71}H_{81}BrN_4O_{12}$
	$C_{70}H_{79}BrN_4O_{12}$
	$C_{69}H_{77}BrN_4O_{12}$
Bromotetramorphia	$C_{68}H_{75}BrN_4O_{12}$
Chlorotetracodeia	$C_{72}H_{83}ClN_4O_{12}$
	$C_{71}H_{81}ClN_4O_{12}$
Chloro-dicodeia-dimorphia	$C_{70}H_{79}ClN_4O_{12}$
	$C_{69}H_{77}ClN_4O_{12}$
Chlorotetramorphia	$C_{68}H_{75}ClN_4O_{12}$

Out of these ten bases four have been prepared, and a substance corresponding in composition with a fifth (chloro-dicodeia-dimorphia) has also been obtained; but from the great similarity in properties between all the five substances and their high formulae, it is clear that no certainty as to the purity of the missing intermediate bodies could exist, and therefore it was not thought advisable to attempt their formation.

2. Action of Hydrobromic Acid on Bromocodide.

When bromocodide hydrobromate (prepared by two hours' digestion of codeia with three times its weight of 48 per cent HBr, precipitation by sodium carbonate, and extraction with ether, &c.) is heated with four to six parts of the same acid to 100° for five or six hours either in a sealed tube or in an open flask, methyl bromide is copiously evolved; the tarry product, dissolved in warm water and precipitated by sodium carbonate, is for the most part insoluble in ether, the insoluble portion having all the properties of bromotetramorphia; the ethereal extract shaken with HCl or HBr yields a viscid liquid, which, on standing, becomes filled with crystals consisting apparently of a mixture of the hydrochlorates, or hydrobromates, of deoxycodeia and a lower homologue, the latter predominating when the digestion is performed in an open flask. Attempts to prevent the formation of the lower homologue by continuing the digestion with HBr for only two or three hours did not succeed, as the large quantity of unaltered bromocodide in the ether extract obtained prevents the separation of the crystalline hydrochlorate or hydrobromate of deoxycodeia, and hitherto no method of separating the deoxycodeia salt from its lower homologue has been arrived at.

The following numbers were obtained by the analysis of these crystals after re-crystallisation from hot water to free them from adhering bromocodide-salt:—

Specimen A, prepared in sealed tubes, digested six hours at 100°:—

0.3185 grm. gave 0.7850 CO₂ and 0.1970 H₂O.
0.2200 grm. gave 0.1025 AgCl.

Specimen B, prepared in an open flask, digested six hours at 100°:—

0.2825 grm. gave 0.6920 CO₂ and 0.1660 H₂O.
0.2260 grm. gave 0.1085 AgCl.

Calculated.		Found.	
Deoxycodeia.	Deoxymorphia.		
C ₁₄ 216	C ₁₇ 204	67.22	66.80
H ₂₂ 22	H ₂₀ 20	6.87	6.54
N 14	N 14		
O 32	O 32		
Cl 35.5	Cl 35	11.53	11.88
319.5	305.5		
C ₁₄ H ₂₁ NO ₄ HCl	C ₁₇ H ₁₉ NO ₄ HCl		

The hydrobromate, prepared from the same batch as specimen B above, gave the following numbers after drying at 100°:—

0.3260 grm. gave 0.7010 CO₂ and 0.1720 H₂O.
0.2730 grm. gave 0.1465 AgBr.

Calculated.		Found.	
Deoxycodeia.	Deoxymorphia.		
C ₁₄ 216	C ₁₇ 204	58.29	58.64
H ₂₂ 22	H ₂₀ 20	5.71	5.86
N 14	N 14	4.00	
O 32	O 32	9.14	
Br 80	Br 80	22.86	22.83
364	350		
C ₁₄ H ₂₁ NO ₄ HBr	C ₁₇ H ₁₉ NO ₄ HBr		

From the above numbers, and more especially from the percentages of H, Cl, and Br found, it appears that while specimen A may have contained some little quantity of deoxycodeia, specimen B must have consisted almost wholly of the lower homologue; to this body the name deoxymorphia may appropriately be given (provisionally), to indicate that its composition bears the same relation to that of morphia as deoxycodeia to codeia.

The numbers required for apomorphia salts are very close to those actually obtained above, viz., for hydrochlorate C=67.22, H=5.93, Cl=11.70; and for hydrobromate C=58.62, H=5.17, Br=22.99; but the entire absence of emetic properties in all these specimens, as observed by Dr. Michael Foster, conclusively proves that this base could not have been present.

Further research is required before it can be decided with certainty which of the three oxygen atoms in codeia is removed in the formation of deoxycodeia; the production of deoxymorphia with simultaneous evolution of methyl bromide, however, indicates that the oxygen that links the methyl group to the rest of the codeia residue is still present in deoxycodeia and deoxymorphia, while the production of both from bromocodide renders the following formulae probable:—

so that deoxycodeia probably bears to codeia the same relation as free hydrogen, H₂, to water, H.OH; or as acetic acid, CH₃.CO.OH, to glycollic, CH₂.OH.CO.OH; bromocodide corresponding similarly to hydrobromic acid, HBr, or to bromacetic acid, CH₂Br.CO.OH.

Experiments are in progress to gain further insight into the structure of the group C₁₇H₁₇NO. By the action of hydriodic acid on codeia methyl is eliminated as iodide, and the elements of free hydrogen and those of HI are added on to this group; from which, as well as from the easy polymerisation to form tetracodeia bases, it appears probable that some at least of the 17 carbon atoms are connected together somewhat after the fashion of ethylene or acrylic acid, which unite readily with HI, HBr, H₂, &c. Again, the oxidising action of AgNO₃ on chlorotetramorphia is accompanied by the production of CO₂, which renders it not improbable that the third oxygen atom exists either as the group [CH(OH)] or as CO.

On carefully examining, side by side, the qualitative reactions of the hydrochlorate B and those of a specimen of pure deoxycodeia-salt from codeia (without evolution of methyl bromide), not the slightest difference was discernible between the two; in their physiological actions, too, as observed by Dr. Michael Foster, the two bodies seem perfectly alike, both being utterly dissimilar from apomorphia, from which in all other respects (qualitative reactions, percentage composition, &c.) they differ either not at all, or extremely little.

The portion insoluble in ether of the batch from which hydrochlorate B was obtained was treated with HCl and fractionally precipitated by strong acid several times successively; this mode of treatment was adopted rather than that with HBr, as a much larger yield is obtained thus, the hydrochlorates of chlorotetracodeia and chlorotetramorphia being much less soluble in dilute HCl than the corresponding brominated bodies are in dilute HBr. Finally, nearly white flakes were obtained, presenting all the characters of chlorotetramorphia hydrochlorate, and yielding the following numbers after drying at 100°:—

0.2480 grm. gave 0.5610 CO₂ and 0.1410 H₂O
0.1390 grm. gave 0.0755 AgCl.

	Calculated.		Found.	
C ₆₈	816.0	61.79	61.70	
H ₇₉	79.0	5.98	6.32	
C ₁₅	177.5	13.44	..	13.45
N ₄	56.0	4.24		
O ₁₂	192.0	14.55		
C ₆₈ H ₇₅ ClN ₄ O ₁₂ ·4HCl	1320.5	100.00		

Hence the portion insoluble in ether must have been bromotetramorphia.

The simultaneous formation of bromotetramorphia and deoxymorphia from bromocodide is explainable in two ways: either

Of these two views, the first involves only known substances and reactions similar to those already known in the codeia series of derivatives, and is, moreover, probable from the circumstance that the numbers obtained in some instances indicate the presence of deoxycodeia as well as deoxymorphia; whilst the second view involves the not improbable existence of bromomorphide, $\text{C}_{17}\text{H}_{18}\text{BrNO}_2$; on the other hand, it will be shown in the next section that equation (III.) represents a reaction which does not readily take place with deoxycodeia, when not in the nascent condition at any rate.

Whichever view be adopted, the ultimate formation of bromotetramorphia requires the action of water on a brominated body, substituting hydroxyl for bromine by a reaction perfectly parallel to that whereby codeia is regenerated from chlorocodide by the action of water,* viz.:—

3. Action of Hydrobromic Acid on Deoxycodeia.

In the hope that this action would give rise to methyl bromide and deoxymorphia, deoxycodeia hydrobromate was heated to 100° for two hours with about five parts of 48 per cent HBr; no change whatever took place, no methyl bromide being found on opening the tube in which the digestion was carried on after complete cooling. After an hour's additional exposure to a temperature of 120°–130°, the contents of the tube were found to have become black and tarry, while a small quantity of methyl bromide floated on the top. Precipitated by sodium carbonate, a very dirty substance was obtained, which was almost insoluble in ether; the ethereal extract, shaken with HBr, gave a small quantity of a tarry hydrobromate, of which 0.1330 grm. gave 0.0790 AgBr, or Br=25.20 per cent, deoxymorphia hydrobromate requiring only 22.86 per cent.

Nothing fit for analysis could be obtained from the portion insoluble in ether, and the minute yield of pure

deoxycodeia from codeia precluded a repetition of the experiment.

4. On the Physiological Action of the Foregoing Codeia Derivatives. By MICHAEL FOSTER, M.A., M.D.

The hydrochlorate of chlorotetracodeia and the hydrobromate of bromotetramorphia, in doses of a decigramme by subcutaneous injection or by the mouth, produced in adult cats in a very few minutes a condition of great excitement, almost amounting to delirium, accompanied by a copious flow of saliva and great dilatation of the pupils. Micturition and defecation occurred in some instances, and vomiting was observed on two occasions with the morphia-salt, but was very slight. The excitement was very peculiar, being apparently due partly to increased sensitiveness to noises, and partly to an impulse to rush about.

The same doses of the morphia-salt given to a young kitten produced the same flow of saliva, dilatation of pupils, and excitement (without vomiting); but the stage of excitement, which in adult cats passed gradually off in a few hours, was followed by a condition marked by a want of co-ordination of muscular movements, and presenting the most grotesque resemblance to certain stages of alcoholic intoxication. This stage was followed in turn by sleepiness and stupor, in which the kitten was left at night; in the morning it was found dead.

Two observations have shown these salts paralyse (in dogs and cats) the inhibitory fibres of the pneumogastric; they also seem to lower the internal tension, but want of material has prevented from ascertaining how this is brought about.

On rabbits neither salt, even in doses of a decigramme, seems to have any effect, except perhaps a slight excitement. There is no dilatation of the pupils, no flow of saliva, and, if one observation can be trusted, no paralysis of the inhibitory fibres of the pneumogastric.

No marked difference was observable between the two salts, except that the morphia salts seemed rather more potent than the corresponding codeia bodies.

The salts of deoxycodeia and deoxymorphia given by mouth or by subcutaneous injection in doses of a decigramme, produced in adult cats, almost immediately after exhibition, a series of convulsions much more epileptic in character than tetanic. In one case there was a distinct rotatory movement.

In a few minutes these convulsions passed away, leaving the animal exhausted and frightened. Then followed a stage of excitement with dilated pupils and flow of saliva, very similar to the effects of the tetracodeia and tetramorphia salts, but less marked.

Doses of half a decigramme given to adult cats produced the stage of excitement only, without the convulsions.

In no case, with any specimen of product, has vomiting been witnessed.

Trials with rabbits gave only negative results. Like the tetracodeia and tetramorphia products, the deoxycodeia and deoxymorphia salts appear to paralyse the inhibitory fibres of the pneumogastric.

No marked differences could be observed between the hydrochlorates and hybromates of deoxycodeia or deoxymorphia.

CHEMICAL AND PHYSICAL ANALYSIS OF SUGAR.*

M. Payen's Process.

This process is based on the insolubility of sugar crystals in alcohol saturated with pure sugar, whilst many foreign matters are soluble in this liquid. The following is the mode of operating:—

An average sample of sugar to be analysed is rubbed lightly in a mortar, so as to break the lumps without

Saccharimetric Optique, Chimique, et Melassesimetricque. By L'Abbé Moigno.

* Matthiessen and Wright, *Proc. Roy. Soc.*, vol. xviii., p. 88.

injuring the crystals. 10 grms. of this sugar are weighed, and placed in a tube about 15 m.m. in diameter, and 30 centims. in length; then about 10 centims. of absolute alcohol are added, to eliminate the 2 or 3 per cent of water which the raw sugar may contain. After shaking the tube it is allowed to settle, and the alcohol decanted. There is then poured into the tube 50 centims. of the test-liquor, which is prepared in the following manner:—

To 1 litre of alcohol of 88° is added 50 c.c. of acetic acid of 7°; in this liquid there is dissolved 50 grms. of dry powdered white sugar. This quantity will saturate the liquid at a temperature of 59° F.; but in order that it may remain saturated in changes of temperature, a string of white sugar-candy crystals is suspended in the vessel which contains the liquor. The solution thus prepared is able to dissolve the uncrystallisable sugar and molasses, to decompose and dissolve succrate of lime, without dissolving the crystals of pure sugar, because it is saturated with the latter.

(The saturated liquor was not quite all that could be wished in some changes of exterior temperature. M. Numa Grar has rendered it more exact by powdering sugar-candy in a mortar, mixing it with the test-liquor, and filtering it; then, on immediate use, it gave comparable results in the valuation of sugar to within a half per cent in the proportion of pure crystallised sugar extracted from the raw sample).

To continue: 50 centims. of this test-liquor are poured into the tube containing the raw sugar which has been washed with absolute alcohol and rapidly drained. The tube is shaken, and allowed to stand, and when the liquor has become clear it is decanted, and a fresh quantity of test-liquor poured in as first; it is again allowed to settle, and again the clear liquor is decanted. It is needful to make a last washing with alcohol of 96° or 98° to remove the saturated liquid interposed between the crystals. There only remains to place the sugar on a filter to dry, and weigh it. The difference between the weight of the sample submitted to analysis and that of the sugar remaining after the process indicates the foreign soluble substances which are mixed with the raw sugar. If the sugar contains insoluble substances, their quantity may be ascertained by dissolving all the remaining sugar in alcohol of 60°, filtering and weighing; the residue remaining on the filter will be the insoluble substances which the sugar contains.

M. Dumas has modified his process, and has rendered it more rapid and more sensitive by directly estimating the foreign soluble matters—the glucose and salts—by the excess of density which the test-liquor presents after the sugar has been washed in it above the density of the saturated solution used in the process. In the practice of this process an ordinary *alcomètre* is all that is needed. The other parts of the process are nearly the same as M. Payen's.

The process is as under: To a litre of alcohol of 85° are added 50 grms. of acetic acid of 80°. To this liquid is added as much pure sugar as it will dissolve; it then marks 74° on the *alcomètre*. On mixing a decilitre of this liquor with 50 grms. of sugar to be analysed, and filtering the liquid, to finish the valuation of the sugar it is only needful to plunge the *alcomètre* into the filtered liquid; if it marks 74° again the sugar is pure; if it descends to 69° the pure sugar is 95 per cent; if it goes down to 64° the pure sugar is 90 per cent. Each degree lost on the *alcomètre* corresponds to a degree of diminution in the richness of the sugar.

In very low-priced sugars, the variable nature of the impurities renders this latter analysis a little uncertain; but for sugars 87° to 100° (of saccharine value), which form the bulk of the sugars of commerce, the results accord with those of the polariscope. If the sugar contains sand or other insoluble matters, they must be taken account of.

In an important refinery in Paris, at Lille, in the most competent hands, in the Customs' Laboratory, and in that

of the Sorbonne, this process has given similar results to the polariscope. In an average of twenty analyses made to determine the richness of a large delivery of sugars of three classes, the difference did not exceed one-thousandth, that is to say, it was *nil*. In a single trial it rarely varies 1 per cent, which is of no account, as we know that the sugars of commerce classed in the same type often differ as much as 8 or 10 per cent in richness.

M. Clerget acknowledges that the old process of M. Payen, although it does not indicate exactly the proportion of pure sugar contained in the raw sugar, gives useful results. He also allows that the process of M. Dumas is very important, not only from its exactitude, but still more so from the simplicity and promptitude of the method; at the same time, he calls attention to this important fact.

It is not sufficient to value the return in crystallisable sugar which may be obtained from saccharine juices—to prove the amount of pure sugar ($C_{12}H_{22}O_{11}$) which the juice contains—because, as is well known, up to the present time it has been found impossible to extract the whole of this, or even a quantity proportionately constant, because of other soluble substances contained in the juice.

Barreswill's Process.

We reproduce this process, although it has been considerably improved, because M. Barreswill was one of the first to attack the difficult problem of sugar analysis. His saccharimetric process is founded on the following facts, discovered by M. Frommers:—

(1). That crystallisable sugar does not reduce the oxide of copper contained in an alkaline fluid.

(2). That it becomes able to reduce this oxide when treated with sulphuric acid, which, by a few minutes' boiling, transforms it entirely into glucose.

(3). The quantity of binoxide reduced is in proportion to the quantity of sugar employed.

When it is required to find the quantity of crystallisable sugar which exists in a liquid, to the exclusion of every other organic product, a standard alkaline solution of oxide of copper must be prepared. By bringing together sulphate of copper, neutral tartrate of potash, and caustic potash, a liquid of an intense blue colour is obtained, which, being filtered, will remain clear and limpid a long time. This solution is the test-liquor, the strength of which must next be determined by ascertaining how much of a solution made with a certain weight of pure dry sugar-candy, with the addition of some drops of sulphuric acid, is needed to decolour exactly a determined volume of it. The test-liquor being thus carefully standardised, a certain quantity of it is placed in a porcelain or glass capsule, and there is then added to it some very concentrated caustic potash, the object of which is to increase the density of the liquid, and render the after precipitation of the oxide of copper more rapid. Then, by means of a graduated burette, the acidified sugar solution is allowed to fall drop by drop into the heated (boiling) test-liquor. As soon as the two liquids are in contact, a yellow precipitate of hydrate of copper appears, which becomes red, and settles to the bottom of the capsule when it has reached the temperature of the liquid in which it is formed. In proportion as the operation advances, the colour of the test-liquor decreases in intensity, whilst the copper is precipitated in a state of protoxide. It is terminated when the solution is entirely decoloured. Then by reading on the burette the number of divisions which it has required to arrive at this limit, we obtain by means of a calculation the quantity of sugar contained in the liquid under examination.

The delicate part of the operation is to seize the point when the precipitation of the oxide of copper is complete. We may arrive at this (if the sugar solution is itself uncoloured) as well by the decolouration of the test-liquor as by the cessation of the formation of the yellow-coloured precipitate, which precedes the deposit of the oxide of copper. The latter is the only test when the liquid to be tested is itself coloured. An excess of sugar solution

added to the test-liquor after the separation of the oxide of copper is complete gives to the solution a brown colour, easily recognised, which results from the reaction of the hydrated alkalis on the glucose.

In cases where the sugar liquid of which the composition is required contains both crystallisable sugar and glucose, the proportion of the latter substance is determined by first making trial with a portion of the liquid brought to a known volume, before it has been submitted to the action of sulphuric acid; the glucose alone reduces the copper solution, which pure sugar leaves intact.

Another portion of the sugar liquid is afterwards boiled with sulphuric acid, so as to convert all the sugar into glucose; by means of a second assay made with the liquor thus modified we have the total weight of the glucose which it then contains; and deducting the weight of the pre-existent glucose obtained by the first operation, we have in the difference the amount of crystallisable sugar contained in the sugar solution (or rather the quantity of glucose which the crystallisable sugar was able to furnish by treatment with sulphuric acid).

When the sugar solution contains (before treatment with acid) only crystallisable sugar, the amount may be ascertained by this method in a quarter of an hour, within 2 or 3 per cent.

The chief fault of this process is that it is only applicable in cases of simple solutions of pure sugar, or of a mixture of pure sugar and glucose. If the sugar to be tested contains tartaric acid, dextrine, or sugar of milk, these substances will act nearly in the same way as crystallisable sugar, and may consequently be confounded with it. On the other hand, there is no doubt of the existence of some organic substances which will reduce the alkaline copper solution in the same manner as glucose itself; in consequence of which this process cannot be employed with absolute certainty, unless by previous experiments it has been proved that other organic substances do not exist in the sugar to be analysed, or that these foreign matters have been properly separated by some efficient method.

Fehling's Copper Liquor.

The improvements mentioned as having been made in Barreswill's process are chiefly in the preparation of the test-liquor, which is called after the inventor. It is prepared as follows:—

"Dissolve 40 grms. of crystallised sulphate of copper in 160 c.c. of distilled water; in a separate vessel which will hold 1 litre place 160 grms. of cream of tartar, 130 grms. of caustic soda, and 500 to 600 grms. of distilled water at the boiling point. The hot alkaline liquor thus obtained dissolves the tartrate of potash very rapidly. The solution of sulphate of copper is then added little by little, when all this salt is dissolved; the litre bottle is filled up with distilled water. The liquor thus obtained is kept in a ground-stoppered bottle."

To standardise the copper liquor:—

"Having provided the liquor as above, the exact standard of it is then determined—i.e., the quantity of sugar which corresponds to a certain volume of this liquor; 10 grms. of pure sugar are dissolved in 80 to 100 grms. of water; 2 or 3 grms. of hydrochloric acid are then added, and by four or five minutes' boiling the sugar is completely converted into glucose. This solution is thrown into a litre bottle, which is filled with distilled water to the gauging point.

Each c.c. of this liquor represents 1 centigram. of pure inverted sugar.

Place 25 c.c. of the copper liquor in a capsule, and raise to the boiling point, when by means of the graduated burette the normal sugar solution falls drop by drop into the boiling copper liquor, until a red precipitate of oxide of copper is formed. Suppose that 15 c.c. of the normal sugar solution have decoloured the tartrate of copper, as each c.c. represents 1 centigramme of sugar, it needs 15 centigrammes of inverted sugar to decolour 25 c.c. of

Fehling's test-liquor. The standard is then represented by 0.15 gm. The process is thus applied to colonial sugar; 10 grms. of sugar are placed in a flask holding 100 c.c., which is then filled up with distilled water. Each c.c. of this liquid represents 0.1 gm. of raw sugar. This liquid is allowed to fall drop by drop, as before, into the vessel containing 25 c.c. of the boiling copper liquor. Suppose that it requires 30 c.c. of the sugar solution, representing 3 grms. of sugar, to decolourise the liquor; the standard of the copper liquor being 0.15 gm. the glucose is found by the following calculation:—

$$\begin{array}{l} 3 \text{ grms.} : 0.15 \text{ gm.} :: 100 : x \\ x = 5 \text{ grms.} \end{array}$$

There is then 5 per cent of glucose in the raw sugar.

Chemical Analysis in its Application to the Sugar Industry.—By M. Feltz.

We are induced to reproduce this clear and practical note because it brings to our notice two instruments used in the sugar industry of Germany—the saccharometer of Balling and the areometer of Brix, with which it is worth while to become acquainted.

When it is wished to value the yield of sugar in a saccharine substance, the ordinary process has been to determine first the amount of crystallisable sugar it contains by the saccharometer. Another weight of the saccharine substance is then burnt, and this furnishes the quantity of ashes. These two known, the return is calculated according to the saline method.

The saccharimetrical method does not require much time. The weighing of a sample is easy and rapid, because there is no need to weigh to a centigramme.*

It is not the same in the determination of the ash. Three-quarters of an hour must be allowed for the incineration of solid saccharine substances, and at least one hour and a half for the evaporation and incineration of a juice or a syrup with the necessary care. Further, incineration, to be carried out with facility, requires apparatus of particular nicety. For an easy method of analysis in the factory it must therefore be renounced.

The saline method is founded on this principle—that the quantity of molasses produced in the manufacture of beet-sugar is proportionate to the amount of salts existing in the saccharine substance.

Another method practised for some time in German sugar factories is based on this—that the quantity of molasses produced is sensibly proportionate to the sum total of the foreign matters contained in the substance, deduction made for the water and the sugar. I shall speak particularly of this process, the result of which is called the *co-efficient of purity*.

Balling graduated an areometer in such a manner that each degree marked upon it corresponded to one per cent in weight of pure sugar dissolved in water. When the areometer known in Germany as Balling's saccharometer,† or Brix's areometer, marks, for example, 15° in a solution of pure sugar, it signifies that in 100 parts of the solution there are 15 of pure sugar.

Juice or syrup from the factory is always a solution of sugar and foreign matters in water. When Brix's areometer is plunged in this solution, this instrument marks a certain number of degrees corresponding both to the sugar and foreign matters in the solution. If, now, by an observation on the polariscope, or by Barreswill's copper method, it is determined how much pure sugar is contained in the solution, it is easy to calculate the weight of the impurities. Suppose that a sugar solution marked 15° on the areometer of Brix, and that saccharimetrical observation indicates 12 per cent of sugar, to obtain the quantity of foreign matters which are found in 100 parts

* 16.350 grms. of pure sugar, combined with 100 c.c. of pure water, gives in Duboscq's instrument a rotation of 100°; therefore 1 centigramme will give the rotation of 0.60 c.; in fact, an inappreciable quantity.

† M. Brix corrected the scale on Balling's instrument, and it is his areometer that is universally used in Germany.

in weight of the solution, it will be sufficient to deduct 12 from 15. Thus of 15 parts of solid matter, 12 are sugar; in 100 parts there will be $12 \times 100 = 80$ parts of sugar, and the co-efficient of purity of this solution is 80. We may remark that by subtracting 15 from 100 we shall have the quantity of water in the sugar liquid.

Thus, two determinations, both quickly made, are sufficient to determine the sugar, the water, and the foreign matters. The determination of the foreign matters is, however, not quite perfect. We have supposed that a degree of Balling or Brix corresponds *exactly* to 1 percent of any substance whatever, which is not strictly correct. It will be found that the weight of foreign substances is always *less* than that indicated; but practically this is of no importance. It is, besides, possible, by a series of experiments, to determine the co-efficient of correction for the areometer in this respect.—*The Sugar Cane.*

ON COLOURS FROM COAL-TAR.*

By HARRY N. DRAPER, F.G.S.

(Continued from p. 297).

To illustrate the manner in which the chemical method of separation is applied, we have arranged here some glasses in which benzol, aniline, and phenol have each been shaken with an acid and an alkali. You will observe that, in the case of benzol, it floats indifferently upon the surface of both acid and alkali; but that the aniline, while untouched by the alkali, is dissolved by and mixes with the acid. The behaviour of phenol is exactly the reverse of this, for the alkali dissolves, while the acid is without action on it. You see in this experiment a general outline of the method by which coal-tar is made to give up the different bodies which it contains. We must, however, pass with some rapidity into detail: and bearing in mind that we have here to do with but five constituents of coal-tar, speak of them one by one as they come before us in their aspect of sources of colour.

By far the most important of these is that which we have here, benzol. To obtain it, the coal-tar oil is distilled by steam heat, and all those portions which boil under 90° on the centigrade scale are collected. Pure benzol is a very volatile, inflammable fluid, of a peculiar odour, forcibly recalling that of coal-gas. It boils at 80°C . It is very much used in the arts as a solvent of india-rubber; and, under the name of *benzine collas*, we are familiar with its employment for the removal of grease stains. When cooled to about the freezing-point of water, it forms very beautiful crystals. This fact is sometimes taken advantage of to effect its separation from the other bodies which accompany it in coal-tar oil. I must ask you to remember, as this is the point from which all we have to say about the colour-giving matters of coal-tar diverges, that benzol was discovered in 1825 by Faraday, who found it as a product of the action of a high temperature on benzoic acid. It is, however, to Hofmann that we owe its recognition as one of the products of the distillation of coal. This discovery was made in 1845.

Much lower down in the diagram you will see the name of another body, aniline, and to this substance I must ask your particular attention. Aniline was discovered in 1826, by Undervorben, who found that indigo gave it as one of the products of its distillation. It has been successively known by the names of "crystalline" and "kyanol," and received its present name from Fritzsche, who, obtaining it by a process only slightly differing from that of Undervorben, named it from *anil*, the Portuguese name of indigo. Aniline, as you see by the diagram, is one of the tar oil constituents; but, as it exists there in very small quantities indeed, it is fortunate that we are not dependent upon this source of it. It is

to Zinin that we owe the knowledge of the simple relations between benzol and aniline, and the fact that the former can be converted into the latter with the utmost readiness.

On referring again to the diagram, we observe that the chemical composition of benzol is thus represented:—

Now, when benzol is mixed with strong nitric acid, a very violent action takes place, and an orange-coloured liquid is formed. When the orange liquid is poured into water, a yellow oil separates and falls to the bottom. This is nitro-benzol. The following equation represents the change which takes place:—

Benzol. Nitric acid. Nitrobenzol. Water.

Nitrobenzol differs remarkably from benzol in its properties. It is, as you see, heavier than water, and its odour is remarkably fragrant, resembling to a considerable extent that of oil of bitter almonds. It is, indeed, known in commerce as artificial bitter almond oil, and is used as a perfume for soap. But it is merely as a step in the process of change which benzol undergoes in becoming aniline that nitrobenzol now interests us. When it is submitted to the action of hydrogen in that condition which chemists call *nascent*, that is just at the instant of its liberation, all the oxygen of the nitrobenzol is removed in the form of water, and, two atoms of hydrogen being introduced, we get *aniline*.

Nitrobenzol.

Aniline.

The method of effecting this change, now universally adopted, is that of Béchamp, which consists in distilling the nitrobenzol with iron filings and acetic acid.

The fact that, under certain circumstances, and more particularly when heated with any substance capable of affording oxygen to it, aniline gave rise to colour, was long known; but no one seems to have attempted to fix any of these colours. It was Runge who first noticed the action of chloride of lime upon aniline; and as this was, perhaps, the earliest experiment in which aniline was seen to give colour, we may repeat it. Here is a solution of a salt of aniline, and you will see that when we add to it a weak solution of chloride of lime, a blue colouration is at once produced. It is important not to add too much of the chloride, for the very agent which produces the colour is most active in destroying it. But though a patent has, indeed, been taken out for making a colouring matter in this way, the process has, I believe, been abandoned, as it is not very practicable.

It is to Mr. W. H. Perkin that we owe entirely the first method by which dye was obtained from tar on an industrial scale. Mr. Perkin was, at the time—in 1856—a pupil of Dr. Hofmann, and was engaged in the endeavour to form, by artificial means, the valuable medicine, quinine. I need not stop to detail here the details of this investigation, but may just say that he was acting upon a compound of toluidine with bichromate of potash. He was, as he tells us himself, surprised to find that, instead of getting quinine, he obtained only a dirty reddish-brown precipitate.

Being, however, desirous to know something more of the nature of this, he tried another base, and was fortunate enough to select aniline. I do not think that unless Mr. Perkin had been a very persevering chemist, we should have been any nearer to coal-tar colours to-day than we were in 1856; for in this case the precipitate was of quite as unpromising appearance as the first; but when it was more carefully examined, he found it to contain a beautiful purple-colouring matter. Here was the first appearance of *mauve*. Now this action of bichromate of potash on aniline will, perhaps, be clearer to you if we make the experiment. Here is a solution of aniline, and we will add to it some bichromate of potash solution. This is, somewhat curiously, the very process which is even now adopted

* A Lecture delivered before the Royal Dublin Society.

in making mauve. This dirty greenish-black precipitate is collected, and dried; it used to be washed with coal-tar naphtha, which removed a troublesome, resinous substance, with which it is contaminated; but this has been given up, and the powder is now treated at once with dilute methylated spirit, which dissolves out the dye; next the spirit is distilled off, and the dye which remains in watery solution is precipitated by the addition of caustic soda; it is then collected on a filter, washed, drained, and dried. Here is some of this aniline purple; it is a solid mass, brittle, and has a very beautiful bronze-like lustre.

We shall have to speak of this property of some of the coal-tar dyes again, so we will not stop to notice it now. Mauve is not very soluble in water, but very readily indeed in alcohol. Its intensity of colour is very remarkable, as I shall be able to show you. Here is a large vessel of water, and we will add to it some mauve, in the proportion of only 1-10th of a grain to a gallon. You see, even with this small quantity, the colour is not only distinct but deep.

This beautiful colour—here is a piece of paper, on which we have fixed it by means of albumen—is so much used now that many of my hearers know, probably even better than I do, that it is one of the “fastest” of the coal dyes, bearing the action of light remarkably well.

Now we have so much before us, that, as regards the chemical constitution of mauve I must only stop to point out to you that it is really a product of the oxidation of aniline; the bichromate of potash giving its oxygen to the base, and itself becoming reduced to sesquioxide of chromium. But no sooner was it ascertained that the action did depend upon oxidation, than the patent office was flooded with specifications, in which it was sought to supplant that of Perkin by effecting the same end by different means. It would be only interesting to chemists were I to read the list of substances which appeared in these specifications, to frame which it would almost seem as if the text-books had been ransacked for bodies capable of giving up their oxygen to aniline. Among those which we may single out, as really practicable, is the process of Dale and Caro, in which chloride of copper is used instead of bichromate of potash.

It was, however, soon discovered that, though a substance might oxidise aniline, it would not necessarily produce mauve; and it was found that there were some reagents, as, for example, nitrate of mercury, tetrachloride of carbon, chloride of tin, &c., which, instead of a purple, gave a crimson colour with aniline.

The discovery of this fact was the earliest step in the history of what is now known as magenta.

Magenta is formed when oxidising agents of a less energetic character than chloride of lime or bichromate of potash act upon commercial aniline. I say, on commercial aniline, because it has been found that pure aniline does not give the colour at all; and it has been found that the impurity—if we may so call it—which is necessary to a successful result, is another body, the name of which we have here on the diagram, and which bears exactly the same relation to the coal-tar product toluol as aniline does to benzol. This toluidine is not put into the aniline for this purpose, but the benzol used for making aniline is selected at such a boiling-point as will ensure the presence of toluol—the mixture being then first formed into a nitro-compound, and finally heated with iron and acetic acid, furnishes the mixture of aniline and toluidine which constitutes the aniline of commerce.

The process which is invariably followed in this country for the manufacture of magenta is that of Medlock. It consists in heating the aniline for some hours with a saturated solution of arsenic acid. This process is effected in a large closed iron vessel set in a furnace and provided with a stirrer. Heat is applied, and the mass is examined from time to time, until the maximum of colour is produced. Water is then added, and steam blown into the apparatus to dissolve the crude dye. The solution is filtered, and common salt is added to it. This throws

down the colouring matter, which is collected again, dissolved in hot water, and set aside to crystallise. The result is in the form of these beautiful crystals, which I owe to the kindness of Messrs. Brooke, Simpson, and Spiller.

I think I can show you the formation of magenta from aniline, if we use, instead of arsenic, another substance, which does not require so much time. Here we have some aniline, and if we mix with it a little chloride of mercury, or corrosive sublimate, it forms a somewhat thick, sticky liquid, which as I heat it slightly, becomes, first, thicker and pasty, and then melts. As soon as it begins to boil the colour comes, and goes on increasing in intensity. It has now become very deep indeed; and you will see this better if I add some alcohol to it, and then pour a few drops into this large jar of spirit. Observe how all the liquid is coloured in a moment.

Magenta, from a chemical point of view, is a salt of a base called rosaniline; and it is a very curious thing, that, while the base is as nearly as possible colourless, the salts are colours of such intensity. Here, for example, is an ammoniacal solution of this rosaniline, and if we add to it an acid—some acetic acid—you see how rapidly it becomes red. Even the carbonic acid of the air can effect this change. So soon as the ammonia evaporates from the liquid, which I have here upon a piece of white paper, we have the crimson colour produced. Or, like most experiments, this may be pleasantly varied if we substitute this white flower for the paper, and, having immersed it in the solution, warm it gently over the gas flame. See how quickly the rose of York becomes that of Lancaster. It has been shown by Dr. Hofmann that when magenta is what chemists call reduced, that is, deprived of part of its oxygen, it is converted into this brown substance, called *leucaniline*. I must not dwell upon this, but may show you that, though acids do not, in the case of rosaniline, develop colour with this substance, it is at once transformed into rosaniline if we give it back its oxygen. Here is a solution of leucaniline, and I will add to it some bichromate of potash solution, which is a very convenient way of getting oxygen into bodies. As we heat the mixture, you will observe the red colour of magenta is at once developed.

You are all as familiar as I am with the colour of magenta; but you see it looks very pretty here, as we have it fixed upon a surface of albumenised paper.

Magenta is now manufactured on an enormous scale, being, indeed, considered rather as a raw material from which other dyes are made than as a dye itself, though, of course, there is a large consumption for it in this way too. As an example of the extent of this manufacture, I may say that, in going over the works of Messrs. Brooke, Simpson, and Spiller, a few weeks since, I was informed that they make 12 tons of aniline weekly; and at the same factory I saw magenta crystallising from a tank which contained 30,000 gallons of its solution. This was certainly the largest tank in the place, but there were some twenty others of smaller dimensions.

(To be continued.)

NOTICES OF BOOKS.

Light Science for Leisure Hours. By RICHARD PROCTOR, B.A. Camb., F.R.A.S., Author of “The Sun,” “Other Worlds than Ours,” “Saturn,” &c. London: Longmans, Green, and Co.

Our newspaper press is each year becoming more scientific, supplying its numerous readers with explanations of the unaccustomed phenomena of Nature, or elucidating technical terms or processes pertaining to some matter of general interest. Mr. Proctor's latest work is a collection of several essays contributed by him from time to time to the various periodicals and the daily press. The main subjects are astronomical or mathematical, but apart from

their intrinsic interest, the articles will well repay perusal on the ground of their bearings politically and historically. Perhaps the most important papers are the first two, in which the phenomena of the aurora, and the variation of the magnetic needle, with their mutual remarkable occurrences, are considered. Here the author's style is very happy; the language is perfectly suited to the general reader, who is gradually led on to understand why spectroscopists have come to the conclusion that the light of the aurora is due to vapour rendered luminous by the passage through it of electrical discharges; while the various speculations as to the nature of the vapour with its peculiar, and, as yet, isolated spectrum, are carefully analysed. The nature of this spectrum is perhaps one of the most interesting scientific questions that have yet to be answered, because its elucidation will tell us also the substance of the zodiacal light, and of the phosphorescence which illuminates at times the nocturnal skies, all these yielding the same spectrum. Of his own views, Mr. Proctor says:—"When once we have reason—as in the case of the aurora we undoubtedly have—to associate electricity with any particular form of luminosity, we seem clearly justified in extending the explanation to the same form of luminosity wherever it may appear. I believe that the key to the whole series of phenomena lies in the existence of myriads of meteoric bodies travelling separately or in systems around the sun. They are consumed in thousands daily by our own atmosphere; they probably pour in countless millions upon the solar atmosphere; and, from what we know of their numbers in our own neighbourhood, and of the probability of their being infinitely more numerous in the neighbourhood of the sun, we have excellent reasons for believing that to them principally is due the appearance of the zodiacal light and the solar corona."

But it is not with such difficult questions that the reader has continually to grapple, for he can, if he pleases, study the fallacies and chances of the odds in the next or latest race, or the peculiarities and rules of the Oxford and Cambridge rowing styles; or again, if his taste be classical, spend an hour with his Homer in considering the genuineness of the description of the shield of Achilles, and find that here, too, has been deep reading, which has given rise to clear thought and happy expression.

CORRESPONDENCE.

THE PHOSPHATE SEWAGE QUESTION.

To the Editor of the Chemical News.

SIR,—If "Superphosphate" were practically acquainted with the manufacture of superphosphate of lime, he would scarcely ask why the native mineral phosphate of alumina is not directly converted into manure, for a solution of it in sulphuric acid does not set and become friable, but remains pasty—a dry pulverulent condition being a *sine qua non* in making artificial manures. The practice with some makers is to use an excess of sulphuric acid in dissolving calcium phosphates in order to ensure a perfect solution, and to dry up the excess of acid with gypsum, but, as "Superphosphate" has learnt from his own experiments, that lime precipitates the phosphates of iron and alumina, this *modus operandi* would be useless as applied to phosphates of alumina, and I cannot see otherwise than that it is an error in manufacturing superphosphates from coprolites (which contain phosphates of Al and iron), to so dry them up, for if the proper quantity of acid is employed, and the coprolites properly ground, the whole of the available phosphates will be dissolved, and the manure be in a good condition; whereas, in an excess of acid, we obtain a pasty product entailing much labour in drying with gypsum, besides the all but inevitable certainty of reducing

some of the soluble phosphate. The condition, too, is never so fine as it should be, and where the superphosphate is sold on an analysis there is a loss of acid and labour which is not met by the higher (if any) results.

My opinion, with regard to phosphates of alumina is that if they were ground to as fine a degree as possible, and mixed with a small percentage of well-dissolved animal charcoal, they might be so distributed in the field with beneficial results. I have always found that superphosphate made from coprolites, with the addition of a small quantity of animal charcoal, are more friable, give better results, both on analysis and in the field, and do not become so "reduced" as those made from coprolites alone.—I am, &c.,

JOHN COX.

Nottingham Mills Company.

MISCELLANEOUS.

Liebig on Germany and France.—At a meeting of the Royal Bavarian Academy of Sciences, on the 28th of March, Baron Liebig spoke thus of the future relations between Germany and France:—"The Academy seizes this moment to declare openly that there exists no national hatred between the German and Latin races. The peculiar character of the Germans, their knowledge of languages, their acquaintance with foreign people, the past and present state of their civilisation, all tend to make them just toward other peoples, even at the risk of often becoming unjust toward their own, and thus it is that we recognise how much we owe to the great philosophers, mathematicians, and naturalists of France, who have been in so many departments our masters and our models. I went forty-eight years ago to Paris to study chemistry; a fortuitous circumstance drew upon me the attention of Alexander Von Humboldt, and a single word of recommendation from him caused M. Gay-Lussac, one of the greatest chemists and physicists of his time, to make to me a young man of twenty, the proposal to continue and finish with his co-operation an analysis which I had commenced; he introduced me as a pupil into his laboratory, my career was fixed after this. Never shall I forget the kindness with which Arago and Thenard received the German student, and how many compatriots, physicians, and others, could I not name who, like myself, gratefully remember the efficacious assistance afforded to them by French men of science in finishing their studies. An ardent sympathy for all that is noble and grand, as well as a disinterested hospitality form some of the most noble traits of the French character."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Polytechnisches Journal von Dingler, second number for May, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Contamination of Iodine with Cyanide of Iodine.—Dr. G. C. Wittstein.—The author first refers to the researches on this subject made by MM. Scanlan, Meyer, and Klobach, the latter of whom found, in a sample of iodine, a quantity of cyanide of iodine amounting to 15 per cent. We further meet here with the results of the analysis of two samples, *a* and *b*—the first being iodine made in the

way, by M. J. Sticht, at New York; the second, another sample of iodine, from which the maker had tried to separate the iodide of cyanogen by means of sublimation. Of sample *a*, 10 grains were weighed off and rubbed up in a mortar, after addition of a few drops of alcohol, with 16 grs. of metallic mercury, until all the free iodine was combined with the metal; the mass was next treated with 14 fluid ounces of water, and the residue insoluble therein collected on a previously-weighed filter, and this next gently dried at 50°. The result was that the material thereon weighed 23.125 grains; consequently the loss (iodide of cyanogen) was 2.875 grains (since $26 - 23.125 = 2.875$); the quantity per cent of iodide of cyanogen in this sample, 28.75. The amount of iodide of cyanogen found in sample *b*, which was tested in the same manner, was found to amount to 56.875. The author observes that Dr. Herzog has found that when iodine, which contains iodide of cyanogen, is treated with metallic iron and water, there is formed a liquid which contains, in addition to proto-iodide of iron, also proto-cyanide of iron. When carbonate of potassa is added to this liquid, all the iron and cyanogen are precipitated and eliminated; and the iodide of potassium thus prepared is quite free from any cyanide of potassium, which, it need hardly be said, is a substance the presence of which should be most scrupulously avoided in a salt like iodide of potassium, which is internally used in large quantities as a medication.

Presence of Baryta in Native Silicates.—Dr. G. C. Wittstein. —Many years ago, the late Professor Mitscherlich, while analysing several specimens of feldspar, found therein baryta, amounting in many cases, to 23 per cent. The author relates that he analysed some fifty samples of native silicates, among which were ten specimens of feldspar (all minerals met with in Bavaria), six of which were found to contain baryta; the highest percentage of that base present amounting to 2.518 per cent, the lowest to 0.3222 per cent, whereby we should observe that in two of the six samples only traces of baryta occurred.

Adulteration of Fuchsine.—Dr. A. Ungerer. —There was given to the author a sample of fuchsine which, having been found insoluble in alcohol, was considered unfit for use. It turned out, on investigation, that this sample of fuchsine consisted of coarsely-ground-up sugar-candy soaked in a very strong solution of fuchsine, so as to exhibit the external physical appearance of that body.

Changes which Flour Undergoes When Kept for a Length of Time.—Dr. Poleck. —The author has instituted a series of researches with the view of ascertaining the cause of the difference exhibited by flour preserved in casks, and that kept in bags, the former of which often obtains a peculiar smell. The author found that the gluten of flour exhibiting that peculiar smell had been, in a great measure, converted into a soluble modification, whereby the flour had lost the capability of being converted into a good dough, the flour also having assumed a sour reaction. The author ascribes the cause of this change to want of a sufficient circulation of air through the mass of the flour kept in casks, the innermost flour in which was most sour and gave off the peculiar somewhat mouldy smell. It was also found that, with this change in the flour, coincides an increase of the albuminous compounds therein soluble in water.

American Journal of Pharmacy, June, 1871.

Omitting the papers and memoirs more particularly relating to pharmacy and pharmacognosy, this number contains the following original papers and essays relating to chemistry:—

Culture of Hops in the United States.—E. Kannal. —Among other particulars more especially bearing upon the amount of production and cultivation of this important article, the author states that he obtained, from 1 lb. of fair commercial hops, 1 ozs. of lupulin, from 1 lb. of fresh New York hops 1 oz, and from fresh Philadelphia hops $\frac{3}{4}$ oz, averaging 1 oz from the lb., or 64 per cent. The smaller yield in the last two cases was due to the fresh condition of the hops. When packed in bales, hops are sometimes adulterated—the outside consisting of good hops, while the interior is filled with hops deprived of the lupulin, and sprinkled over with lycopodium and powdered resin to hide the fraud.

Note on Hydrocyanate of Morphia.—Dr. J. M. Maisch. —After first referring to the fact that, among the descriptions of morphia salts, as furnished by various chemists, the hydrocyanate is not enumerated; in Gmelin's "Chemistry," some double hydrocyanates are mentioned, but not the simple morphia salt, of which, as far as the author knows, nothing is known of its formation or properties. The following contain the results of the experiments as thus far obtained:—(1) A neutral solution of a morphia salt, even if diluted to the proportion of 1 : 1500 (1 grain in 31 ozs.), yields, with a neutral soluble cyanide, a crystalline precipitate consisting of hydrocyanate of morphia. (2) After the crystals have separated, the filtrate, acidulated with nitric acid, yields no precipitate with iodo-hydrargyrate of potassium; the morphia hydrocyanate, therefore, if soluble at all, dissolves but very sparingly in water. (3) The solubility of morphia hydrocyanate appears not to be increased by an excess of the precipitant. (4) The precipitate is readily dissolved if the liquid is slightly acidulated by a mineral acid; it is likewise soluble in acetic acid. Hydrocyanic acid does not precipitate a neutral solution.

Detection of Turmeric in Powdered Rhubarb and Yellow Mustard.—Dr. J. M. Maisch. —A small quantity of the suspected rhubarb is agitated for a minute or two with strong alcohol, and then filtered, chrysophanic acid being sparingly soluble in this menstruum. The brown yellow colour of the filtrate is due to the resinous principles of rhubarb mainly; if adulterated with turmeric, the tincture will be of a brighter yellow shade; a strong solution of borax produces, in both tinctures, a deep red-brown colour. If now pure hydrochloric

acid be added in large excess, the tincture of pure rhubarb will instantly assume a light yellow colour, while the tincture of the adulterated powder will change merely to a lighter shade of brown red. The test is a very delicate one, and is based on the liberation of boric acid, which imparts to curcumin a colour similar to that produced by alkalies, while all the principles of rhubarb soluble in strong alcohol yield pale yellow solutions in acid liquids. The same test, applied in the same manner, is also applicable to ground mustard seed. The seeds of *Sinapis alba* yield a powder of a yellow-grey colour, entirely distinct from the colour of yellow mustard met with in the trade. Agitated with alcohol, and filtered, a turbid solution is obtained, which assumes a bright yellow colour on the addition of the borax solution, and becomes colourless or whitish again on being supersaturated with hydrochloric acid. If the mustard be coloured with turmeric, the filtrate has a yellow tint, becomes brown-red by borax, and retains the colour on addition of hydrochloric acid. All the so-called yellow mustard of commerce which the author has had occasion to examine, whether ground in England or in the United States, contains turmeric, a practice which ought to be discontinued; for, under the yellow colour imparted by turmeric, adulteration of mustard may be carried on to an almost indefinite extent, if strength be supplied by the addition of a little capsicum.

Testing Cochineal.—J. M. Merrick, jun., S.B. —The author takes 24 grms. of the drug, previously ground to powder, and boils that quantity in a capacious narrow-necked flask, with 750 c.c. of distilled water, for one hour. The liquid is immediately filtered through dry paper-filters, and tested when cold in the following manner:—50 c.c. are measured off and poured into another flask of about 200 c.c. cubic capacity, and the measuring vessel rinsed with a definite quantity of water, say 10 to 15 c.c.; a weak solution of permanganate of potassa is then run in from a burette with a glass cock, the flask being well shaken after the addition of every 10 c.c. of the permanganate solution (this does not, as does solution of bleaching-powder, precipitate the colouring matter of the cochineal), so much is added as to change the colour of the cochineal solution to a very faint pink shading on yellow, but never reaching a full yellow; this pink shade should be persistent, that is to say, it should not turn yellow after standing for fifteen minutes. The principal points in this practically very good method are—The use of a weak solution of permanganate; to have a very faint pink colour as a standard of comparison; to let the liquids remain, after agitation, together ten to fifteen minutes before comparing them. The author concludes his paper by observing that very little can be told of the value of a sample of cochineal by a mere physical examination, while the frequent inconsistency between value and price is equally surprising, the author having known samples to differ 30 per cent in colouring power and only one or two cents per pound in price.

Revue des Cours Scientifiques de la France et de l'Etranger (double number), June 8, 1871.

This number does not contain any original papers bearing upon chemistry or allied sciences.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 9, 1871.

This number contains the following original papers and memoirs:—

Derivation of the Relation of the Heat of Gases under Permanent Pressure and Volume from the Mechanical Theory of Heat.—Dr. P. Mohr. —This paper, and the following lengthy essay by the same author—

Doctrine of Molecules.—Are not suited for useful abstraction.

Determination of what might be not inaptly termed Chemical Longitude and Latitude—viz., the Exact Situation and Locality occupied by the CH₃ in Aromatic Compounds.—G. Gräbe. —Illustrated with diagrams.

Contribution to our Knowledge on the Sulpho-Nitrogen Acids.—A. Claus. —This lengthy paper contains the preliminary record of the results of the author's experiment on the mode of preparation and some of the properties of a compound which appears to have the formula SO₂.NO₂K. This is obtained by mixing together freshly-prepared solutions of sulphurous acid in strong alcohol and a concentrated solution of nitrite of potassa in water (prepared by passing a current of nitrous acid gas into a concentrated solution of carbonate of potassa). Since the compound, the formula of which is above-mentioned, is insoluble in alcohol, it is thrown down, along, however, with some nitrite of potassa, from which it is to be freed by cautious washing with a little cold water. The compound is very prone to decomposition also by heat, even below 100°. When treated with some water and peroxide of lead at a temperature not exceeding 40° to 45°, an intensely violet-coloured solution of trisulphoxy-azotate of potassa, [NO₃(SO₃K)], is formed, which salt is obtained in solid state by cooling the solution down to below 0°.

New Series of Aromatic Hydrocarbons.—Th. Zincke. —The second instalment of a monograph on this subject, treating on the oxidation of diphenyl-methan and benzyl-toluol. Diphenyl-methan or benzyl-benzol, C₆H₅—CH₂—C₆H₅, is difficultly oxidised, and yields mainly benzo-phenon, C₆H₅—CO—C₆H₅. Benzyl-toluol, structural formula C₆H₅—CH₂—C₆H₄—CH₃, yields, by strong oxidation, among other products, an acid of the formula C₁₁H₁₀O₂; when the oxidation is less violent, an acid, C₁₁H₁₂O₂. The greatest portion of this part of the essay is devoted to the enumeration and description of a large number of salts of these acids.

Action of Sodium upon the Two Isomeric Monobromotoluols.—W. Longinucci.—The contents of this paper are essentially, by the author's own confession, parallel to those, and almost identical with the contents of a paper on this subject, recently published by Dr. Zincke. The main products of the action of sodium upon monobromotoluols are ditolyl, and a fluid body boiling at between 277° and 282° , $C_{11}H_{11}$.

Aceto-Sulpho Acid.—C. Bender.—The acid just named is, in free state, a colourless, syrupy liquid. The author describes a series of salts of this acid, among which we quote the following:—Aceto-sulphate of baryta, $(CH_3CO.CH_2SO_3)_2Ba + H_2O$, crystallises, forming nacreous shining lamellae; loses its water at 100° . Lead-salt, $(CH_3CO.CH_2SO_3)_2Pb + H_2O$, has an acid reaction, crystallises, fuses at 140° , and is decomposed at 170° . Copper salt—

a bluish green-coloured salt, crystalline, and, like the other salts, soluble in water and dilute alcohol.

Quantitative Spectrum Analysis.—K. Vierordt.—An algebraico-physical paper.

Preliminary Communication on the Electrolysis of the Substituted Derivatives of Acetic Acid.—G. E. Moore.—The author represents the decomposition of pure cyan-acetate of potassium by electrolysis by the following formula:—

The author is engaged in more accurately investigating the various products of this decomposition.

Short Notice on Isomeric Iodobenzoic Acids.—P. Griess.—The author communicates that some five years ago he prepared isodisalic acid, obtained by the action of hydriodic acid upon sulphuric diazo-salicylic acid. The new acid alluded to is a crystalline body, difficultly soluble in water, but readily so in alcohol and ether, and fusing at 152° .

Test for the Detection of Small Quantities of Sulphur present in Coal-Gas.—Dr. V. Wartha.—The author forms, first, before the blowpipe, in the loop of a platinum wire, a bead of pure soda, and next passes this bead over the edge of the gas flame, after which the bead is held in the interior of the flame in order to deoxidise the sulphates and sulphites of soda into sulphuret of sodium; the bead is then transferred to a porcelain basin, crushed, and some nitro-prusside of sodium added, whereby the smallest trace of sulphur will be detected. This reaction is fifty times more sensitive than that upon silver-foil; and the test can be performed in about three minutes, whereas Dr. Vogel's sulphur-copper reaction for this purpose takes four hours.

Les Mondes, June 22, 1871.

This number does not contain any original papers bearing upon chemistry or allied sciences.

Annalen der Physik und Chemie, von Poggendorff, No. 4, 1871.

This number contains the following original papers and memoirs:—**Pendulum Observations.**—Dr. O. E. Meyer.—Illustrated with engravings.

Periodicity of the Heliographical Dispersion of the Sun's Spots.—Dr. F. Zöllner.

Weber's Compensated Magneto Meter for Measuring the Intensity of the Gas Magnetism.—Dr. F. Kohlrausch.

Refraction and Dispersion of the Light in the Chloride, Iodide, and Bromide of Silver.—W. Wernicke.—An algebraico-optical paper, an observation also applicable to the following paper.

Huyghen's Eyepiece.—Dr. J. B. Listing.

Combination of Sulphuric with Nitric Acid.—Dr. R. Weber.—The author caused the vapours of sulphuric anhydride to pass into very pure and highly concentrated nitric acid, care being taken to cool the flask containing this fluid very considerably by means of ice. By carefully experimenting, there is thus formed a crystalline substance, which, after having been drained by being placed on porous bricks, yields very deliquescent well-defined crystals soluble in water, thereby causing an elevation of temperature. This solution, on being tested with potassium iodide, only produces a very faint yellow colouration, thereby indicating that traces only of nitrous acid are present. The analysis, executed according to a method described here at length, but not presenting any new feature, led to the result that the formula of the body here alluded to is $4SO_3 \cdot NO_2 \cdot 3HO$. In 100 parts, as found by experiment—Sulphuric acid, 66.22; nitric acid, 23.44; water, 11.25. As calculated according to the formula—Sulphuric acid, 66.40; nitric acid, 22.41; water, 11.19.

Construction of Filtering Apparatus According to Bunsen's Apparatus.—E. Zettnow.—This description cannot be understood without the reproduction of the engravings.

Appendix to my Paper "On the Influence the Concentration of Saline Solutions has upon the Electromotive Force."—Dr. L. Bleekrode.—The addition to a lengthy essay published by the author in this periodical some years ago.

Green Pigment of Leaves.—Dr. J. J. Müller.—A paper illustrated with engravings and treating on the spectrum phenomena

exhibited by the leaves of various kinds of plants viewed in strong sunlight.

Critical Remarks on Dr. Andrews's Paper on the Ice Calorimeter.—Prof. R. Bunsen.

Observations on the Ice Calorimeter.—Dr. C. Bohn.

Observations on the Theory of the Oceanic Currents, as set forth by Dr. Witte.—A. Coleridge.

Microscopical Structure of Hailstones.—Dr. P. Reinsch.—A paper illustrated by engravings, and, as the immediately preceding and following, chiefly algebraico-physical as regards the contents.

Conduction of Heat in Layers of Liquids.—Dr. Despretz.

NOTES AND QUERIES.

Temperature of the Sea.—I have consulted Fownes, Miller, Watts, Berzelius, &c., but, though most of them give the composition of the water of the English Channel, none of them mention its temperature. By supplying this information in your next number you would greatly oblige.—THERMO.

Kelp Liquors.—I use wrought-iron pans for boiling down my kelp liquors, which average 50° T.: towards the latter stages of concentration, I find they act upon the iron rendering the salts black. Can you inform me of the cause, and if there is any remedy?—IODINE MANUFACTURER.

A Problem in Chemistry.—The following novel question is taken from the chemistry paper set at the preliminary examination of the Royal College of Surgeons, on June 22:—"I give you £2, or £2 10s. to purchase some chemicals and chemical apparatus. Give a list and price, as near as may be, of the various articles you would purchase."—M.C.

TO CORRESPONDENTS.

T. W. F.—This correspondent has sent us the following letter. In reply, we beg to inform him that if he sends stamps to our publisher he will supply him with the Nos. of the *CHEMICAL NEWS*, which will be more convenient than our reprinting the articles:—"I am indeed sorry to trouble you in a manner like this, but I shall be exceedingly glad if you will give me particulars as to preparation and purification of chloral hydrate, as I have no work on the subject, nor have I those numbers of the *CHEMICAL NEWS* that contains the desired information. I have no means of getting to see them, either, in this neighbourhood. I have only lately begun to take your valuable paper in. Of course I want the simplest and cheapest method. In your next will oblige."

G. Lunge.—Thanks for your communication.

J. Cox.—Received with thanks.

E. F.—The work has not yet appeared.

Royal 8vo., pp. 388, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling,

A Concise View of the Law connected with Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentee's Manual."

London: Longmans, Green and Co., Paternoster Row.

BERNERS COLLEGE of CHEMISTRY.

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W

THE
QUARTERLY JOURNAL OF SCIENCE,
AND
ANNALS OF MINING, METALLURGY, ENGINEERING, INDUSTRIAL ARTS,
MANUFACTURES, AND TECHNOLOGY.

Edited by WILLIAM CROOKES, F.R.S., &c.

On Friday next, No. XXXI., July, 1871, price 5s., Illustrated.

CONTENTS.

- I. The Dawn of Light Printing.
 - II. Pneumatic Transmission. By FREDERIC CHARLES DANVERS, A.I.C.E.
 - III. An Essay towards Establishing a Science of Money. By A LONDON MERCHANT.
 - IV. Where are the Bones of the Men who made the Unpolished Flint Implements? By WILLIAM PENGEELY, F.R.S., F.G.S.
 - V. Experimental Investigation of a New Force. By WILLIAM CROOKES, F.R.S., &c.
 - VI. Molecules, Ultimates, Atoms, and Waves, by Mungo Ponton, F.R.S.E.
 - VII. A New Mechanical Agent: a Jet of Sand.
 - VIII. British Service Ordnance. By S. P. OLIVER, Lieut. Royal Artillery.
- Notices of Books. Progress of the Various Sciences. Recent Scientific Literature, &c., &c.
- London: Offices of the Quarterly Journal of Science, 3, Horse-Shoe Court, Ludgate Hill, E.C.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.
Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.
Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.
Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.
Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND CO., 20, King William Street, Strand.

AMSTERDAM EXHIBITION, 1869.

THE GRAND DIPLOMA OF HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar, Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers: all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

STEATITE.

Above can be had in quantity, free on board or rail, Portsoy, Banffshire, N.B.—Apply to W. Ross Hutton and Co., Chemical Works, Burghhead.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

W. NEILL & SON'S
PATENT BLOWING ENGINES,
ACID PUMPS, AND DONKEY PUMPS,
ESPECIALLY ADAPTED FOR
WELDON'S PATENT CHLORINE PROCESS.

W. NEILL and SON have just Patented most important improvements in the Air-Valves of Blowing-Engines, which enable them to secure the most perfect "Cut-off" at the termination of each stroke, together with a perfectly free inlet and outlet for the Air at the proper time, thus securing a much better result from each stroke of the Air-Piston, with greater freedom of action, also a very great saving in the wear and tear of valves.

These improvements are of especial advantage to Engines working under the comparatively high pressure of blast required in the Weldon Process.

W. Neill and Son have supplied Blowing Engines and Pumps to all the principal Alkali Makers who have adopted the Weldon Process, and are ready to furnish Plans and Estimates for the erection (with the latest improvements) of the whole of the Plant required.

Efficiency and Simplicity of Construction, with the best workmanship, guaranteed. References on application.

W. NEILL and SON, ENGINEERS, &c.,

ON THE GASEOUS AND LIQUID STATES OF MATTER.*

By THOMAS ANDREWS, M.D., F.R.S.,
Vice-President of Queen's College, Belfast.

THE liquid state of matter forms a link between the solid and gaseous states. This link is, however, often suppressed, and the solid passes directly into the gaseous or vaporous form. In the intense cold of an Arctic winter hard ice will gradually change into transparent vapour without previously assuming the form of water. Carbonic acid snow passes rapidly into gas when exposed to the air, and can with difficulty be liquefied in open tubes. Its boiling-point, as Faraday has shown, presents the apparent anomaly of being lower in the thermometric scale than its melting-point; a statement less paradoxical than it may at first appear, if we remember that water can exist as vapour at temperatures far lower than those at which it can exist as liquid. Whether the transition be directly from solid to gaseous, or from solid to liquid, and from liquid to gaseous, a marked change of physical properties occurs at each step or break, and heat is absorbed, as was proved long ago by Black, without producing elevation of temperature. Many solids and liquids will for this reason maintain a low temperature, even when surrounded by a white-hot atmosphere, and the remarkable experiment of solidifying water, and even mercury, on a red-hot plate, finds thus an easy explanation. The term spheroidal state, when applied to water floating on a cushion of vapour over a red-hot plate, is, however, apt to mislead. The water is not here in any peculiar state. It is simply water evaporating rapidly at a few degrees below its boiling-point, and all its properties, even those of capillarity, are the properties of ordinary water at 96.5° C. The interesting phenomena exhibited under these conditions are due to other causes, and not to any new or peculiar state of the liquid itself. The fine researches of Dalton upon vapours, and the memorable discovery by Faraday of the liquefaction of gases by pressure alone, finished the work which Black had begun. Our knowledge of the conditions under which matter passes abruptly from the gaseous to the liquid, and from the liquid to the solid state, may now be regarded as almost complete.

In 1822, Cagniard de La Tour made some remarkable experiments, which still bear his name, and may be regarded as the starting-point of the investigations which form the chief subject of this address. Cagniard de La Tour's first experiments were made in a small Papin's digester, constructed from the thick end of a gun-barrel, into which he introduced a little alcohol and also a small quartz ball, and firmly closed the whole. On heating the gun-barrel with its contents over an open fire, and observing from time to time the sound produced by the ball when the apparatus was shaken, he inferred that

after a certain temperature was attained the liquid had disappeared. He afterwards succeeded in repeating the experiment in glass tubes, and obtained the following results:—An hermetically-sealed glass tube, containing sufficient alcohol to occupy two-fifths of its capacity, was gradually heated, when the liquid was seen to dilate, and its mobility at the same time to become gradually greater. After attaining to nearly twice its original volume, the liquid completely disappeared, and was converted into a vapour so transparent that the tube appeared to be quite empty. On allowing the tube to cool, a very thick cloud was formed, after which the liquid reappeared in its former state.

It is singular that in this otherwise accurate description, Cagniard de La Tour should have overlooked the most remarkable appearance of all, the moving or flickering striæ, which fill the tube when, after heating it considerably, the temperature is quickly lowered. This phenomenon was first described by myself in 1863, as it is seen in carbonic acid, which has been partially liquefied by pressure, and afterwards heated a little above 31°. It may be observed on a larger scale and to great advantage by heating such liquids as sulphurous acid or ether in hermetically-sealed tubes.

The experiments whose results I am about to describe have occupied me for a period of fully ten years; they involved the construction of novel forms of apparatus, in which the properties of matter might be studied under varied conditions of temperature and pressure, such as had never been realised before. In my earlier attempts I endeavoured, as others had already done, to use the expansive force of the mixed gases which are disengaged in the electrolysis of water; and I was able in this way to obtain pressures of 150 atmospheres and even more in glass tubes; but the method was in many respects defective, and more than one dangerous explosion occurred, so that I eventually abandoned it.

In the apparatus finally adopted, the gas to be compressed is enclosed in a long glass tube, of which the greater part of the length, or about 450 millimetres, has a capillary bore, and the remainder, about 150 millimetres, an internal diameter of 2 millimetres. The free capillary end is sealed, while the gas in a pure and dry state is passing through; while at the other end the gas is confined by a movable column of mercury. The details of the method by which this is accomplished will be found in the Bakerian lecture for 1869, to which I must also refer for an account of the process by which the original volume of the gas at the freezing-point of water, and under one atmosphere of pressure was determined, and also the volumes of the same gas deduced from the observed measurements when it was compressed at different pressures in the capillary tube.

A conical protuberance on the capillary part of the tube, a little above its junction with the wider part, corresponded as nearly as possible with a hollow cone in a stout brass flange, the joint being rendered perfectly tight by careful packing. The body of the apparatus consisted of two

* Read before the Royal Institution of Great Britain, June 2, 1871.

cold-drawn copper tubes of great strength, to the ends of which four massive brass flanges were firmly attached. Two corresponding flanges or end pieces, each carrying a fine steel screw packed with great care, were bolted on the lower flanges. The success of the experiments depended greatly on the packing of this screw. It was effected by means of a number of leather washers, tightly pressed down and saturated *in vacuo* with melted lard. The apparatus was now filled with water; the flanges with the glass tubes, one containing the gas to be examined, the other air or hydrogen to act as a manometer or measure of the pressure, were bolted down upon the upper flanges of the copper tubes. The joints had always leather washers interposed; and when sufficiently tightened, they resisted any pressure which could be applied, even for an indefinite time. The two copper tubes were connected by a fine horizontal tube, so that the whole of the interior of the apparatus was in free communication. The pressure was obtained by screwing one or other of the steel screws into the water. I have recently had the apparatus constructed of iron and filled with mercury. As mercury is much less compressible than water, the same length of screw produces a greater pressure on the interior of the apparatus, even with a larger cavity. There are other advantages in this form of the apparatus which I hope will facilitate future research. The objection to it is its extreme sensitiveness to changes of temperature, so that a variation of $\frac{1}{1000}$ th of a degree alters the internal pressure by several atmospheres.

In the actual experiments the gas under examination does not come into view till it has entered the capillary tube, and is exposed to a pressure of thirty or forty atmospheres. The limit of the pressure which can be obtained has hitherto been the capacity of resistance of the glass tubes to bursting. Fine thermometer glass tubes of white glass will frequently burst when exposed to a pressure of little more than 100 atmospheres; but green glass tubes of good quality are much stronger, and will easily bear a pressure of 300 atmospheres. One of the strongest forms of glass capillary tube for resisting internal pressure is obtained by drawing out a thick green glass tube, heated to softening, till it becomes so fine as to be flexible. Tubes of this kind can easily be drawn out at the blowpipe table, and obtained of very uniform bore. I have compressed air in such tubes to $\frac{1}{1000}$ th of its ordinary volume without bursting the tubes.

Two rectangular brass cases, closed before and behind with plate-glass, surround, one the manometer, and the other the tube containing the gas to be examined, and allow them to be maintained at any required temperature by the flow of a stream of water. The manometer was maintained as nearly as possible at the temperature of the apartment; the tube containing the gas, on the contrary, was maintained at different temperatures, according to the object in view. The following observations, published in 1863, contain the results of my earliest experiments on this subject:—"On partially liquefying carbonic acid by pressure alone, and gradually raising the temperature at the same time to 88° F., the surface of demarcation between the liquid and gas becomes fainter, loses its curvature, and at last disappears. The space is then occupied by a homogeneous fluid, which exhibits when the pressure is suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout its entire mass. At temperatures above 88° no apparent liquefaction, or separation into two distinct forms of matter could be effected, even when a pressure of 300 or 400 atmospheres was applied. Nitrous oxide gave analogous results."

The flickering striæ referred to can be admirably shown, as I mentioned before, in hermetically sealed tubes of strong glass, partially filled with such liquids as sulphurous acid or ether. The liquid must in the first instance be heated a few degrees above what I have designated the "critical" point. The appearances exhibited by the ascending and descending sheets of matter of unequal

density are most remarkable, but must be seen in order to be understood. They only occur in this striking form in fluids heated a little above the critical point, and are produced by the great changes of density which slight variations of pressure or temperature produce in this case. They are always a clear proof that the matter in the tube is homogeneous, and that we have not liquid and gas in presence of one another. These striæ are, in short, only an extraordinary development of the movements seen in ordinary liquids and gases when they are heated from below. The experiments to be immediately described will explain their great intensity above the critical point.

When the temperature falls below the critical point, the formation of a cloud indicates that we have now heterogeneous matter in the tube, fine drops of liquid in presence of a gas. We must take care, however, not to suppose that a cloud necessarily precedes the formation of true liquid. If the pressure be sufficiently great no cloud of any kind will form.

I now proceed to describe the general results of the experiments upon carbonic acid. If a certain volume of carbonic acid at the temperature of 13.1° and under a pressure of one atmosphere be exposed to a gradually-increasing pressure, its volume will steadily diminish, but at a faster rate than according to Boyle's law, till at the pressure of 48.9 atmospheres its volume is reduced to about $\frac{1}{10}$ th of the original volume at one atmosphere. Liquefaction now begins and continues with very slight augmentation of pressure, the necessity for which I traced to the presence of a minute quantity of air (about $\frac{1}{1000}$ th part) in the carbonic acid. On augmenting the pressure after liquefaction, the volume slowly diminished, but at a much faster rate than in the case of ordinary liquids. Later experiments carried to much higher pressures have fully confirmed this result. At 21.5° similar results were obtained, but a pressure of nearly 60 atmospheres was required before liquefaction began.

At 30.9° C., or 87.7° F., the critical point of temperature is reached. It is the temperature at which liquid ceases to be formed under any pressure. At a temperature a little below this point the surface of separation between liquid and gas becomes very faint and loses its curvature, the density and other physical properties of the liquid and gas being now identical and the tube filled with homogeneous matter. If the temperature and pressure be kept steady, no evidence of heterogeneity will be obtained by optical tests under the most varied conditions of volume.

If we now follow the course of a given volume of carbonic acid gas at 31.1°, or 0.2° above the critical point, we shall find that its course resembles that of the gas at lower temperatures till the volume is reached at which liquefaction might be expected to begin. A rapid but not (as in the case of the formation of liquid) abrupt fall then supervenes, after which the carbonic acid undergoes a slow diminution of volume as the pressure augments. The curves, which are here exhibited as they were represented in the Bakerian lecture, illustrate very clearly these statements. We have thus carbonic acid at 0.2° above the critical point, and at a pressure of 73 atmospheres behaving very nearly as if it liquefied. At this pressure an augmentation of only $\frac{1}{10}$ th of the entire pressure diminishes the volume of the carbonic acid to about one-half. Yet during the whole of this fall, no evidence of heterogeneity, or of two states of matter present together in the tube, could at any period be obtained. Carbonic acid at this temperature of 31.1°, and under a pressure of 75 atmospheres, behaves much more as a liquid than as a gas when the pressure is either augmented or diminished; yet it never exhibits under any conditions the characteristic properties of the liquid state; that is to say, no surface of separation is formed by change of pressure, nor will it collect into drops and form a cloud.

At 32.5° the fall, when liquefaction might be expected, is less abrupt than at 31.1°; and at 35.5°, although still manifest, it is further reduced. At 48.1° the fall shown at

lower temperatures can no longer be distinctly observed, and the curve representing the change of volume approximates to that of a perfect gas. There can be little, if any, doubt that at a higher temperature carbonic acid would behave under augmenting pressures nearly as nitrogen or hydrogen.*

I have frequently exposed carbonic acid, without making precise measurements, to much higher pressures than any of the foregoing, and have made it pass without break or interruption from what is regarded by every one as the gaseous state, to what is, in like manner, universally regarded as the liquid state. Take, for example, a given volume of carbonic acid gas at 50° C., or at a higher temperature, and expose it to increasing pressure till 150 atmospheres have been reached. In this process its volume will steadily diminish as the pressure augments, and no sudden diminution of volume, without the application of external pressure, will occur at any stage of it. When the full pressure has been applied, let the temperature be allowed to fall till the carbonic acid has reached the ordinary temperature of the atmosphere. During the whole of this operation no breach of continuity has occurred. It begins with a gas, and by a series of gradual changes, presenting nowhere any abrupt alteration of volume or sudden evolution of heat, it ends with a liquid. The closest observation fails to discover anywhere indications of a change of condition in the carbonic acid, or evidence, at any period of the process, of part of it being in one physical state and part in another. That the gas has actually changed into a liquid would, indeed, never have been suspected, had it not shown itself to be so changed by entering into ebullition on the removal of the pressure. For convenience, this process has been divided into two stages, the compression of the carbonic acid and its subsequent cooling; but these operations might have been performed simultaneously, if care were taken so to arrange the application of the pressure and the rate of cooling that the pressure should not be less than 76 atmospheres when the carbonic acid had cooled to 31°.

We are now prepared for the consideration of the following important question. What is the condition of carbonic acid when it passes, at temperatures above 31°, from the gaseous state down to the volume of the liquid,

* These different modes of passing from the gaseous to the liquid state are admirably illustrated by a solid model constructed by Prof. J. Thomson, which was exhibited at the lecture. I have been favoured by Prof. Thomson with the following description of this model:—

"The model combines Dr. Andrews's experimental results in a manner tending to show clearly their mutual correlation. It consists of a curved surface referred to three axes of rectangular co-ordinates, and formed so that the three co-ordinates of each point in the curved surface represent, for any given mass of carbonic acid, a pressure, a temperature, and a volume, which can co-exist in that mass.

"In Dr. Andrews's diagram of curves, published in his paper in the *Transactions of the Royal Society for 1869*, p. 583, the experimental results, for each of several temperatures experimented on, are combined in the form of a plane curved line referred to two axes of rectangular co-ordinates. The curved surface in the model is obtained by placing these curved lines with their planes parallel to one another, and separated by intervals proportional to the differences of the temperatures to which the curves severally belong, and with the origins of co-ordinates of the curves situated in a straight line perpendicular to their planes, and with the axes of co-ordinates of all of them parallel in pairs to one another, and by cutting the curved surface out so as to pass through those curved lines smoothly or evenly.

"The curved surface so obtained exhibits in a very obvious way the remarkable phenomena of the voluminal conditions at and near the critical point of temperature and pressure in comparison with the voluminal conditions throughout other parts of the indefinite range of gradually varying temperatures and pressures. This curved surface also helps to afford a clear view of the nature and meaning of the continuity of the liquid and gaseous states of matter. It does so by its own obvious continuity throughout the expanse to which it might be extended round the outside of the critical point in receding from the range of the points of pressure and temperature where an abrupt change of volume can occur by gasification or condensation. On the curved surface in the model, Dr. Andrews's curves for the temperatures 13.1°, 21.5°, 31.1°, 35.5°, and 48.1° centigrade, from which it was constructed, are shown drawn in their proper places. The model admits of easily exhibiting in due relation to one another a second set of curves in which each curve would be for a constant pressure, and in which the co-ordinates would represent temperatures and corresponding volumes. It serves generally as an aid towards bringing the whole subject clearly before the mind."

without giving evidence at any part of the process of liquefaction having occurred? Does it continue in the gaseous state, or does it liquefy, or have we to deal with a new condition of matter? If the experiment were made at 100°, or at a higher temperature, when all indications of a fall had disappeared, the probable answer which would be given to this question is that the gas preserves its gaseous condition during the compression; and few would hesitate to declare this statement to be true, if the pressure were applied to such gases as hydrogen or nitrogen. On the other hand, when the experiment is made with carbonic acid at temperatures a little above 31°, the great fall which occurs at one period of the process would lead to the conjecture that liquefaction had actually taken place, although optical tests carefully applied failed at any time to discover the presence of a liquid in contact with gas. But against this view it may be urged with great force, that the fact of additional pressure being always required for a further diminution of volume is opposed to the known laws which hold in the change of bodies from the gaseous to the liquid state. Besides, the higher the temperature at which the gas is compressed, the less the fall becomes, and at last it disappears.

The answer to the foregoing question, according to what appears to me to be the true interpretation of the experiments already described, is to be found in the close and intimate relations which subsist between the gaseous and liquid states of matter. The ordinary gaseous and ordinary liquid states are, in short, only widely separated forms of the same condition of matter, and may be made to pass into one another by a series of gradations so gentle that the passage shall nowhere present any interruption or breach of continuity. From carbonic acid as a perfect gas to carbonic acid as a perfect liquid, the transition we have seen may be accomplished by a continuous process, and the gas and liquid are only distant stages of a long series of continuous physical changes. Under certain conditions of temperature and pressure, carbonic acid finds itself, it is true, in what may be described as a state of instability, and suddenly passes, with evolution of heat and without application of additional pressure or change of temperature, to the volume, which by the continuous process can only be reached through a long and circuitous route. In the abrupt change which here occurs, a marked difference is exhibited, while the process is going on, in the optical and other physical properties of the carbonic acid which has collapsed into the smaller volume, and of the carbonic acid not yet altered. There is no difficulty here, therefore, in distinguishing between the liquid and the gas. But in other cases the distinction cannot be made; and under many of the conditions I have described it would be vain to attempt to assign carbonic acid to the liquid rather than the gaseous state. Carbonic acid, at the temperature of 35.5°, and under a pressure of 108 atmospheres, is reduced to $\frac{1}{10}$ of the volume it occupied under a pressure of one atmosphere; but if anyone ask whether it is now in the gaseous or liquid state, the question does not, I believe, admit of a positive reply. Carbonic acid at 35.5°, and under 108 atmospheres of pressure, stands nearly midway between the gas and liquid; and we have no valid grounds for assigning it to the one form of matter any more than to the other. The same observation would apply with even greater force to the state in which carbonic acid exists at higher temperatures and under greater pressures than those just mentioned. In short, the passage under great pressures from the liquid to the gaseous state may be effected by the application of heat without break or breach of continuity. That a marked change in the physical properties of the substance occurs during this process is no objection to its being continuous. If mercury as a liquid is opaque and as a gas is transparent, the red and translucent bromine, on the other hand, when heated above the critical point, becomes so opaque as almost to resemble a mass of resin. Frankland has shown that the flame of hydrogen becomes continuous when the

gas is burned under a pressure of 20 atmospheres, and these experiments have been since extended by the same able chemist and Lockyer. We must not, however, suppose that one intermediate state exists between liquid and gas; on the contrary, an infinite succession of intermediate states may truly be said to connect the liquid proper and the gas proper; in other words, the passage is continuous. When the critical point is attained, the density of the liquid and gas becomes the same, and the tube is filled with homogeneous matter.

As regards the question of the continuity of the solid and liquid states, it would be necessary, in order to establish this continuity, to obtain, by the combined action of heat and pressure, the solid and liquid of the same density and of like physical properties. To accomplish this result will probably require pressures far beyond any which can be reached in transparent tubes; but it may be possible to show by experiment that the solid and liquid can be made to approach to the required conditions.

ON A LAW IN CHEMICAL DYNAMICS.*

By JOHN HALL GLADSTONE, Ph.D., F.R.S.,
and ALFRED TRIBE, F.C.S.

It is well known that one metal has the power of decomposing the salts of certain other metals, and that the chemical change will proceed until the more powerful metal has entirely taken the place of the other. The authors have investigated what takes place during the process.

The experiments were generally performed as follows:—72 c.c. of an aqueous solution of the salt of known strength, and at 12° C., were placed in a tall glass; a perfectly clean plate of metal of 3230 square millimetres was weighed and placed vertically in this solution without reaching either to the top or bottom; the action was allowed to proceed quietly for ten minutes, when the plate was removed, and the deposited metal was washed off. The loss of weight gave the amount of metal dissolved, and represented the chemical action.

The most complete series of results was with copper and nitrate of silver.

In the earlier terms of this series, twice the percentage of silver-salt gives three times the chemical action. The

close agreement of the observed numbers with those calculated on this supposition as far as the 9th term, is shown in the fifth and sixth columns. The law then breaks down, and after about 7 per cent the increased action is almost in direct ratio with the increased strength.

The position of the plate in the solution was found to make no difference to this 2.3 law.

Similar series of experiments were made with zinc and chloride of copper, zinc and sulphate of copper, zinc and nitrate of lead, iron and sulphate of copper, and other combinations; and in every instance where the solution was weak and the action simple, the law of three times the chemical change for twice the strength was found to hold good.

It was proved that the breaking down of the law at about 3.5 per cent of salt in solution was irrespective of the quantity of the liquid, or of the time for which the plate was exposed. With 72 c.c. of a 1.41 per cent solution of nitrate of silver the rate of action remained sensibly the same for as long as twenty-five minutes, notwithstanding the constant deposition of silver. This apparently paradoxical result is due to fresh relays of the original solution being brought up to the plate by the currents produced, and that period of time elapsing before any of the products of decomposition are brought back again in their circuit.

When it was perceived that within easily ascertainable limits the chemical action is the same for similar consecutive periods of time, experiments were made in far weaker solutions. It was only necessary to lengthen the time of exposure. It was thus found that the law of three times the chemical action for twice the strength of solution holds good though at least eleven terms of the powers of two; in fact, from a solution that could dissolve 1 grm. of copper during the hour, to a solution that dissolved only 0.000001 grms., a million times less.

The manner in which the silver is deposited on a copper plate was examined, and the currents produced were studied. At first a light blue current is perceived flowing upwards from the surface of the plate, presently a deep blue current pours downwards, and these two currents in opposite directions continue to form simultaneously. A similar phenomenon was observed in every case where a metallic salt attacked a plate of another metal. The downward current was found to be a solution of almost pure nitrate of copper, containing about three times as much NO_3 as the original silver solution, while the upward current was a diluted solution of the mixed nitrates. Moreover, the heavy current took its rise in the entangled mass of crystals right against the plate, while the light current flowed from the tops of the crystalline branches. It was evident that when the fresh silver was deposited on these branches, and the fresh copper taken up from the plate, there was not merely a transference of the nitric element from one combination to another, but an actual molecular move of it towards the copper plate, producing an accumulation of nitrate of copper there, and a corresponding loss of salt in the liquid that is drawn within the influence of the branching crystals. Hence the opposite currents.

The amount of action in a circuit of two metals and a saline solution must have as one of its regulating conditions the conducting-power of that solution. It appeared by experiment that a strong solution of nitrate of silver offers less resistance than a weak one; and it was also found, on adding nitrate of potassium to the nitrate of silver, and its power of attacking the copper plate was increased; that the augmentation of the foreign salt increased the action still further; and the 2.3 law holds good between two solutions in which both the silver and potassium salt are doubled, though it does not hold good if the quantity of foreign salt be kept constant. Similar results were obtained with mixed nitrates of silver and copper.

While these later experiments offer an explanation of the fact that a solution of double the strength produces more than double the chemical action, they do not explain

* Abstract of a paper read before the Royal Society, June 15, 1871.

why it should produce exactly three times the effect, or why the ratio should be the same in all substitutions of this nature hitherto tried. The simplicity and wide range of the 2-3 law seem to indicate that it is a very primary one in chemical dynamics.

ON THE DETERMINATION OF AVAILABLE CHLORINE IN BLEACHING POWDER.

By GEORGE LUNGE, Ph.D., F.C.S.

IN the last issue of the CHEMICAL NEWS there is, reprinted from the *American Chemist*, a paper by Mr. Herreshoff, describing a new method for the determination of available chlorine in bleaching powder. This method is founded on the well-known reaction between potassium bichromate and stannous chloride. I have nothing to say against its principle, and it may very likely yield accurate results in practice. But it must suffer under the disadvantage common to all volumetric methods based upon the application of stannous chloride, viz., the change which the solution of the latter undergoes so rapidly that it requires to be re-standardised for every new series of tests. This alone would be a drawback to the general introduction of Mr. Herreshoff's plan, but apart from it, the *raison d'être* which its author gives for the new method, and without which it does not seem to be called for at all, is, in my opinion, contrary to facts. He finds "the methods now in general use inconvenient, and, unless executed with the utmost care, liable to much inaccuracy," and he alleges against Penot's arsenic method (the only one he quotes, and certainly the best) several disadvantages. Now this method, as modified by Mohr, is so extremely easy of execution, quick and accurate that I believe most chemists will require strong reasons for inducing them to give it up for Herreshoff's or any other method. The disadvantages, however, which Mr. Herreshoff enumerates do not at all exist in fact, as I shall prove *seriatim*.

He says: "arsenious acid is with difficulty purified, and there is no convenient method by which to test its purity." It is, perhaps, not very pleasant work to re-sublime arsenic, but not at all difficult; besides, it can be easily avoided; at least I have never experienced any difficulty whatever in obtaining perfectly pure arsenious acid from the dealers in pure chemicals. Nothing, again, is more convenient than to test for its purity; heat (of course under a protecting hood) a little of the arsenic in a porcelain capsule, covered with another, and remove the second capsule when a little sublimate has been formed. If this sublimate shows no reddish tint, but is of a pure white, there are no sulphides in the arsenic, as they are more volatile than the arsenious acid, and sublime first. Then continue to heat till all arsenic is volatilised, and convince yourself that no fixed residue is left.

He says, further: "The standard solution of sodic arsenite is tedious to prepare, from the fact that it requires a long time for complete solution of the required amount of arsenic in sodic carbonate solution." This I do not understand at all. If the arsenic is finely pulverised, and if the quantities of sodium carbonate and water as prescribed in the usual text-books (say Fresenius or Mohr) are employed, I have always found that a few minutes after the liquid was fully boiling the arsenic was completely dissolved. It need then only be left to cool, and filled up to the required volume, and the standard solution is ready.

Lastly: "This solution will not keep with certainty for any length of time, and is newly standardised only with difficulty." It is well-known that Mohr has found out the cause of the arsenite solution sometimes becoming oxidised, viz., the presence of oxidisable sulphur compounds in the arsenic or the sodium carbonate employed. If such are avoided, and nothing is easier, then the arsenite solu-

tion keeps good for years. Mohr mentions that he found it unchanged after four years. I, for my part, have never had an opportunity of trying it for such a long period, as my stock of solution never lasted more than a few months at a time, but for some time I made a regular practice of testing the very last portion of the standard solution, which was kept in a large sized bottle, standing with its mouth upwards, and exposed to the light, and I never found the standard in the least changed. Nor can I see any trouble in re-standardising. I do it by means of iodine solution which has been first standardised itself with a small quantity of pure arsenic. I prefer, in opposition to Mr. Herreshoff, to run the arsenite solution into the iodine solution, as this more nearly corresponds to the operation in actual bleaching powder testings. In these the end of the reaction is tried on a piece of filtering paper moistened with a solution of starch containing a little potassium iodide. I find that the brown spots produced by the testing vanish again in a day or so, and the same paper, spread on a large porcelain crucible cover and kept from dust, lasts scores of times over again.

These are all the objections Mr. Herreshoff makes against Penot-Mohr's method, and I think they all fall to the ground. So far this method must be considered not only one of the best, but also the easiest and simplest for bleaching powder estimations.

ON COLOURS FROM COAL-TAR.*

By HARRY N. DRAPER, F.G.S.

(Continued from vol. xxiii., p. 308.)

Now the quantity of crimson dye which is given by coal is, if we consider the question of weight only, by no means large. Here is a block of coal, which weighs 100 lbs., and here in succession are the quantities of tar, naphtha, benzol, nitrobenzol, aniline, and magenta which the 100 lbs. of coal give. See how sudden is the transition; notice how absurdly insignificant seems the quantity of magenta given by this large mass of coal. This smallness of quantity is, however, compensated to a great extent by the marvellous intensity of the colour. I think I can give you some idea of this. You will see, in the first place, that the quantity of wool which the magenta in this bottle will dye is nearly as large as that of the coal itself. But there is a very simple way of illustrating this in a striking manner. Here are two sheets of paper. One of them has been dusted over with some magenta, in fine powder, and the other with mauve. The colour-giving substances are there, but, at least to those of you who are at a distance, they are scarcely visible. But if we direct a stream of alcohol against the paper, you will see the latent colour develop itself in a very beautiful manner.

This experiment may be varied in a charming manner. Here you have a bouquet of apparently white flowers, on which I, before the lecture, dusted some of these dyes. On projecting a stream of alcohol upon them you will see, however, that they assume tints which, though I cannot say of them that each is exactly appropriate to the flower on which it appears, are at least sufficiently pretty.

In making magenta on the large scale which I have mentioned, there are large quantities of residuary products; and as it is important that these should be made as profitable as possible, they have been, of course, examined by the manufacturer. One result of this has been the discovery of the very beautiful orange colour which we have here, and though it is known in commerce as *phosphine*, chemists will recognise it better as a salt of chrysianiline.

This dye cannot be made at will, but is invariably formed in making magenta, and is separated during its purification. It gives, as you see, a very beautiful yellow orange tint, and is much used to produce scarlets, by first dyeing the

* A lecture delivered before the Royal Dublin Society.

silk or wool in magenta, and then passing it through a bath of phosphine.

Here is also a brown, which is one of these residual colours.

I spoke just now of magenta as being a raw material from which other dyes were produced, and we will now proceed to examine some of the means by which it is made to give blues and violets, and even greens. The most important process for making blues is that in which the magenta is heated with a further quantity of aniline. The process takes some time, and the mixture, which first becomes purple, changes finally to a very beautiful blue. This is what is known as "*bleu de Lyon*." It is, unfortunately, not soluble in water, and several methods have been adopted to make it so. The one most usually employed is exactly like that which is used with indigo for the same purpose, namely, treatment with sulphuric acid. A sulpho-acid is formed, and the result is a blue completely soluble in water. Here is a solution of this blue, the tint of which is very beautiful.

But, perhaps, the most interesting of the aniline blues is that called "*Nicholson's blue*." I cannot tell you how this is prepared, as the process has not been made the subject of a patent, but I can show you the blue itself. It is perfectly soluble in water, and what is most curious is, that, like salts of rosaniline, it is almost completely decolourised by alkalis. I have here an alkaline solution of this colouring matter which has been prepared before the lecture, and we will immerse this skein of silk in it, and then wash it well with water. If, now, we put the silk into water containing a little sulphuric acid, you will see the blue developed at once. This process of dyeing blue is now very extensively employed.

The fact that the combination of aniline with magenta gave rise to violets and blues, led Dr. Hofmann to suppose that other bodies might supply the place of the aniline. He found that this was actually the case, and that the bodies known to chemists as iodide of ethyl and iodide of methyl could be substituted for aniline with most successful results. This discovery has given rise to an entirely new series of colours, known in trade as "*Hofmann's*." The iodide of ethyl, or of methyl, is heated with the magenta, just as in the case of the aniline, and this beautiful violet is the first result. The tint obtained much depends upon the quantity of iodide used; becoming bluer, and even greener, as it is in excess. Perhaps the most interesting point in this process is, however, that if the quantity of iodide of ethyl is properly proportioned, a most beautiful green is the result. Here we have it in solution, and here is paper dyed in it. I think this is one of the most beautiful and most natural colours in the whole coal-tar series, though, where all are so beautiful, it is difficult to assign the place of honour to any one. The great advantage of this green is that it is at least as beautiful a colour by gaslight as by daylight. But it has the most remarkable property of being changed by exposure to heat. It differs, as I said, from the violent dyes only in containing more iodide of ethyl than they do. But this excess of iodide can be removed by heat; and if we pass this piece of paper, which has some of the green dye on it, over the flame of the lamp you will see an almost immediate change to violet. The degree of heat required is so near to that which chars the paper that I do not think this need be alarming to ladies who sit too near the fire. It might, however, be made the means of securing a charming variety in costume.

When I tell you that from the final residuum from these manufactures, when all the colour has been got out, especially from Dale's process for making violet, a very intense black is obtained, you will have formed some idea of the capability of aniline as a dye-producing material. This black is used largely in the manufacture of printing ink.

But we must now pass to the consideration of some of the other coal-tar constituents which produce colour, and I regret that our time is so short that we cannot speak

of them, except in the briefest manner. The first of these which we shall notice is *phenol*. Here is a beautiful specimen of this body, which I owe to the kindness of Dr. Calvert of Manchester, who is the manufacturer of it in all the forms in which we find it in common. To you it is perhaps more familiar as *carbolic acid*, and its use as a disinfectant and as a remedy for toothache are sufficiently well known. We have only now to consider it as a producer of colour. At the beginning of this lecture I showed you the colour produced by phenol itself when a solution of chloride of iron is added to it. Had we time for the experiments we should find that this colour-giving property is shared by almost every compound of this body. One of the most interesting of these is *rosolic acid*. This body is procured by heating phenol with a mixture of sulphuric and oxalic acids. In commerce it is known as *aurine*. You see it here, in a fine specimen which Dr. Calvert has sent me, as a resinous mass having a greenish metallic lustre. When this substance is heated with ammonia it forms a very intensely coloured compound, which you will see produced when we add ammonia to the powdered acid in this dish. *Aurine* is used for dyeing this orange tint on silk, of which we have a specimen here. But if instead of merely adding the ammonia it is heated with rosolic acid in a closed vessel under pressure, there is found a new substance known as *peonine*, which was lately very extensively, and is still, I believe, to some extent, used as a dye for woollens. I ought here to mention that this dye has been said to have a specifically poisonous action, and to produce blistering where the fabrics dyed with it were worn next the skin. It is, however, easily recognised, Dr. Calvert tells me, by the bleaching action exercised on it by a solution of sulphurous acid. When peonine is heated with aniline, it is converted into the blue colour called "*azuline*," which at one time was manufactured on a very large scale, but has now been replaced by the blues I have already brought before you.

Then when phenol is heated with nitric acid a very violent action takes place, and the body called *carbazotic* or *picric acid* is produced. This body forms very beautiful crystals, and is much used in dyeing the beautiful yellow shade of which we have an example here, and also in giving green shades when combined with the blue colours. *Picric acid*, in its turn, gives with cyanide of potassium a crimson dye which, when converted into an ammonia salt, is identical with the beautiful colouring matter called *murexide*, a colour formerly obtained from animal sources.

Next we pass to *naphthaline*, a substance which is a positive trouble to gas manufacturers, and in choking up the mains becomes a fruitful source of that discontent which all of us express at one time or another in reference to our gas supply.

Naphthaline, too, has been made to give colours; and though I am passing over a subject which would afford material for at least an entire lecture, I can only call your attention to two colouring matters derived from it. One of these is called "*Manchester yellow*," and is much used in colouring soap; the other is a *naphthaline brown*. For specimens of both of these colours, I am indebted to the kindness of Messrs. Roberts, Dale, and Co., of Manchester, who are manufacturers of them.

One of the most cherished aims of those who have experimented on the products of the destructive distillation of coal has been the production from some of them of the colouring matter of *madder*. Some idea of the importance of this problem may be gathered from the fact that the total growth of this plant is estimated to amount to 47,500 tons, having a value of £2,150,000. England alone pays no less than £100,000 annually for the madder with which are produced the red, purple, and black printed calicoes for which she has become famous. All this money is paid to foreign countries, for England does not cultivate madder. But if we have not madder of our own, we possess coal, and every new use we can make of this becomes a new source of wealth. It is known that all the various tints, which, with different mordants, are given by madder,

are due to a substance called *alizarine*. Now it was discovered so recently as last year that this body, *anthracene*, which you see here as a coal product, and a specimen of which I hold in my hand, is capable, when treated in a suitable manner, of giving a colouring substance which is in every respect the same as the *alizarine* of madder. I regret exceedingly that we cannot now go into the details of this subject, but I introduce it to you notice because a lecture on the coloured derivatives of coal-tar would be wanting in the last and most interesting link which has been added to the subject were it to be altogether omitted.

I may, however, just say that this discovery is due to two German chemists, Messrs. Graebe and Liebermann, and that the manufacture of artificial *alizarine* is being carried on both by them in Germany, and by Mr. Perkin in England. Mr. Perkin has made a most important step on the industrial application of the discovery, for he has recently taken out a new patent in which is made a very important modification of the original process, which was too expensive to be of real commercial importance. It is interesting to find Mr. Perkin in 1856 the pioneer of the entire industry of the coal-tar colours, and now in 1870 intimately connected with that which will yet most probably prove to be the most important discovery which has yet been made in connection with it.

I may say, too, that at present there is a difficulty in the way of the application of this means of making *alizarine*, and this is the comparative scarcity of *anthracene* itself. Two thousand tons of coal give only 1 ton of *anthracene*; and until this quantity can be increased either by improved methods of operation, or until some other product of coal-tar—*naphthaline*, perhaps—can be converted into *anthracene*, the production of artificial *alizarine* will not attain to that commercial importance which is certainly in store for it.

I will now endeavour to show you how readily the dyes from coal-tar attach themselves to silk and wool, and thus illustrate experimentally the very simple process of dyeing with them. For silk and wools no mordants are used, as the affinity of these substances for the colours is very great.

Here are solutions of *magenta*, of *Hofmann's violet*, and of *picric acid*, and you see we have only to pass the skeins through them in order to dye them in a moment. But the colours do not possess this affinity for linen or cotton. I can show you this, I think. Here I have a pattern embroidered in silk on a cotton ground, and if we pass this through a solution of *magenta* you see it becomes uniformly coloured. But if we now leave it for a few minutes in dilute ammonia you will see that the dye is nearly removed from the linen, while the silk retains a beautifully deep tint.

You will naturally inquire how, then, the coal-tar dyes are applied to linen and cotton fabrics. Sometimes they are mordanted with tannin, which has the property of fixing the dye; but the usual plan is to print the colour in combination with white of egg—albumen—and then to coagulate the mixture by heat. Here is an egg which we have boiled hard, and if we put it into this warm solution of *magenta*, you will get a very good idea of the affinity of these colours for albumen. Now, you see it has become completely dyed. The consumption of albumen for this purpose is enormous, and is said to amount in one French province alone, where these dyeing and printing operations are carried on, to 300,000 pounds weight a year.

The coal-tar dyes have received many other applications besides those to dyeing and printing articles of wearing apparel. They have been employed to colour starch, and muslin stiffened with those starches looks very pretty indeed; they have been made the bases of printing and lithographic inks; are largely used in paper-staining; they are also employed in making coloured writing inks. *Naphthaline yellow* is used in giving a yellow tint to fancy soaps. Lastly, I may say that travellers have found ros-

aniline replacing rouge and henna on the cheeks and nails of Eastern ladies.

Before I leave a subject which has insensibly drawn me on much further than I intended, I must ask your attention to the beautiful bronze-like reflection which some of the aniline colours possess.

This appearance is common to all of them, to a greater or less extent; but I think the one which has it in the greatest intensity is the *Hofmann violet*.

Here is a large sheet of glass, over which we have spread some of this colour, which you see is of the most lovely purple by transmitted light, but reflects a tint like that of some varieties of tropical beetles, or the tail-feathers of the peacock. This fact has of course not escaped attention, and has been used in the decoration of several kinds of leather goods, of straw hats, and even of articles made of iron and steel. It is interesting to notice that the reflected colour is exactly the complementary of the colour transmitted.

It is not easy to obtain statistics of a manufacture like this of the coal-tar colours. I have already given you a few figures in reference to *magenta*, and to these I may now add, that the united gas works of Europe are capable of furnishing 53,000 cwts. of *magenta*, and that the estimated value of all the tar dyes made is about a million and a quarter pounds sterling annually.

You will see from the series of colours we have arranged here, that this black coal acts, so to speak, the part of a prism, and gives tints which extend from one end of the spectrum to the other; and, indeed, almost approach in brilliancy the natural spectrum.

It was once said of a celebrated divine, that he had not only exhausted his subject, but his hearers too; and as I do not wish you to say this of me, I will detain you no longer. There was an old story about a farthing's worth of iron, which, when made into chronometer springs, became worth a thousand pounds. In the industry we have been considering, we have a parallel to this. Dirt has been well-defined as "matter in the wrong place." This is just what coal-tar was before the discovery of these colours. When it could be made into mauve and *magenta*, it soon got into its right place, and has become a new means of employing labour, and a new source of wealth; for the almost useless tar gave a dye which, at the time of its discovery (it is cheaper now) sold, if not for its weight in gold, at the price of platinum.

I am painfully conscious of the imperfection of my attempt to lay before you this subject as I could have wished, but I cannot conclude without pointing out that these discoveries have arisen entirely from results obtained—not in trying to make dyes, but in studying chemistry for chemistry's sake. *Hofmann*, *Perkin*, *Nicholson*—all those whose names are intimately connected with the manufacture of colours from coal-tar—were students of pure chemistry. And tracing back from this large industry, which is slowly, but surely, changing the position of England from that of a colour-importing to that of a colour-exporting country, we come upon the name of him who, in discovering benzol, became the parent of it all. And it cannot be without encouragement to the student to note that the earnest study of Nature alone raised the book-binder's apprentice to the high position which Faraday occupied as a philosopher and teacher; that if Nature is in this respect like death,

"Pulsat æquo pede pauperum tabernas regumque turres,"

and confers her favours alike on rich and poor, she yet is the truest type of perpetual life; that Faradays yet to come may, while sitting at her feet, and

"Nourishing a youth sublime

With the fairy-tales of science and the long results of time,"

look forward, like him whom we have lost, to the period when, to use the language of an elegant writer, "the sun of truth will arise in unclouded brilliancy, and place them in the enjoyment of that intellectual light which has ever been among the holiest aspirations of the human race."

EXAMPLES FOR PRACTICE IN QUANTITATIVE ANALYSIS.

By ALEXIS A. JULIEN.

(Continued from vol. xxiii., p. 290).

Example No. 6.—Analysis of Calcic Carbonate.

This is a pure precipitated calcic carbonate.

A. Determination of CaO.—Weigh out 1 to 1½ grms., throw into a beaker, moisten, add dilute HCl in excess, cover, heat to boiling until all CO₂ is expelled, add sufficient ammoniac oxalate (Table II.), and then (NH₄)₂O in slight excess, cover, and set aside over night. Decant carefully upon a filter, wash by decantation with boiling water, and transfer to the filter, taking care, before the addition of a fresh portion, to wait until the fluid has completely passed through the filter. If any particles of the precipitate cannot be rubbed from the sides of the beaker, dissolve them in a few drops of highly dilute HCl, add (NH₄)₂O, and transfer to the filter. The precipitate, when dried, is removed from the filter as thoroughly as possible, the filter burned on a platinum wire, and the whole treated in either of the following three ways:—

Conversion into CaO.—This method is especially applicable to small quantities of precipitate, under half a gramme, and consists in a strong ignition to bright redness over a blast-lamp, until the weight remains constant.

Conversion into CaCO₃.—The ashes of the filter are emptied into the hollow of the lid of the crucible, the lid is placed inverted on the crucible, and the latter heated, at first very gently, then more strongly, until the bottom reaches a very faint redness, and is so kept from ten to fifteen minutes, removing the lid from time to time. Cool, weigh, moisten with a little water, and test this after a time with a minute slip of turmeric paper. Should the paper turn brown, rinse off the slip of paper, throw in a small lump of (NH₄)₂CO₃, evaporate to dryness (best on the water-bath), heat to very faint redness, and weigh. If the weight has increased, repeat the same operation to constant weight.

Conversion into CaSO₄.—Moisten the precipitate with pure concentrated H₂SO₄, and ignite, or ignite it with pure (NH₄)₂SO₄, to a low redness, and repeat the operation to a constant weight, with the use of dilute H₂SO₄.

B. Indirect Determination of CO₂.—The apparatus required consists of a flask (50 c.c.), with a doubly perforated stopper, through which on the one side a tube passes down to the bottom of the flask, while its outer end is closed with a piece of rubber tubing and of glass rod. The tube which passes through the other perforation of the stopper is terminated just below the cork, while its outer end is connected, after a triple bend, with a tube filled with CaCl₂, which has not been over-ignited. The calcic carbonate is weighed in a small tube of just sufficient length to stand up at first in the flask. A sufficient quantity of dilute HCl is introduced into the flask, the tube inserted, the cork adjusted, and the whole carefully wiped and weighed. The tube is then upset, and the acid gradually allowed to decompose the carbonate. The liquid is then gently heated, the wax stopper is displaced by a tube filled with CaCl₂, air is drawn through the apparatus by means of an aspirator to the extent of six times the volume of the flask, the wax stopper is replaced, the whole cooled completely, wiped, and weighed. The loss in weight represents the CO₂.

Example No. 7.—Analysis of Limestone.

A. Main Analysis.—Dissolve 2 grms. in HCl and a little HNO₃, in a covered beaker, heat to boiling, transfer to a casserole, evaporate to dryness, moisten with HCl, dissolve in hot water, and filter.

(a). Determination of SiO₂.—Wash, dry, and ignite the residue, mix it with six parts of Na₂CO₃, fuse in a pla-

tinum crucible, soften the fused mass with water, acidify with HCl, evaporate to dryness, moisten with HCl, dissolve in hot water, filter, wash, dry, ignite, and weigh. Result, SiO₂.

(b). Determination of Al₂O₃ and Fe₂O₃.—Unite the filtrate from (a) to the main filtrate, add a little NH₄Cl and then (NH₄)₂O in the slightest possible excess, boil a few minutes to expel the excess of (NH₄)₂O, filter rapidly, keeping the beaker and funnel carefully covered, wash thoroughly, dry, ignite, and weigh. But if the precipitate is bulky, re-dissolve in a little HCl, and divide the solution accurately; in one half, re-precipitate with a slight excess of (NH₄)₂O as before, boil, filter, wash, dry, ignite, and weigh. Result, Al₂O₃ and Fe₂O₃ (and P₂O₅, if present in the limestone). In the other half, reduce the solution and determine the Fe volumetrically, as directed farther on, in Example No. 9.

(c). Determination of CaO.—Unite all the filtrates and washings from (b), heat to boiling, add sufficient ammoniac oxalate (Table II.) and (NH₄)₂O in slight excess, and then proceed exactly as in Example No. 6, A. Re-dissolve the calcic oxalate in HCl, re-precipitate with (NH₄)₂O in excess, filter, wash, dry, and ignite. Result, CaO.

(d). Determination of MgO.—Unite the filtrates and washings from c, concentrate as much as possible, and precipitate the MgO exactly as in Example No. 2, A.

B. Determination of CO₂.—Employ one of the methods in Example No. 6, B.

C. Determination of S and P₂O₅.—Moisten 6 grms. of limestone with water, digest with HNO₃ until solution, evaporate to dryness, re-dissolve in HNO₃, dilute, filter, wash, and divide the solution.

(a). Determination of S.—In one half, dilute very largely, heat to boiling, add Ba₂NO₃ in slight excess, and proceed as in Example No. 2, B. Result, the entire amount of S in the limestone, occurring both as SO₃ and as S in the sulphides.

(b). Determination of P₂O₅.—To the other half of the solution add 100° c.c. of ammoniac molybdate, stir, keep near the boiling-point several hours, and set aside over night in a warm place. Then decant on a ribbed filter, if the supernatant liquid is colourless, and transfer precipitate to filter by means of small portions of the filtrate. Rinse the beaker and wash the precipitate once with the diluted precipitant. Heat the filtrate and washings to boiling, add a little more of the precipitant, and set aside, to determine if any more P₂O₅ will be precipitated. Dissolve the precipitate back into the original beaker by pouring dilute (NH₄)₂O through the filter. If a red residue of oxide of iron remains undissolved, pour dilute HNO₃ upon it, allow it to pass into the (NH₄)₂O solution, acidulate that with HNO₃, boil, add more of the precipitant, and set aside as before, filter, and wash several times with the diluted precipitant, then dissolve the precipitate on the filter, and adhering to the beaker in as little as possible dilute (NH₄)₂O into a small beaker. Add HCl almost to neutralisation, and from 1 to 10 c.c. of magnesia mixture, and continue as in Example No. 2, A.

D. Determination of SO₃.—Dissolve 5 grms. in a little HCl, evaporate nearly to dryness, dilute, filter, and wash. Heat to boiling, add sufficient BaCl₂ (Table II.), and continue as in Example No. 2, B. Result, the SO₃ actually occurring in the limestone. If the S in this amount be deducted from that found in C, a, the amount of S of the sulphides will be obtained.

E. Determination of H₂O.

(a). Direct Determination.—The apparatus required consists of a piece of hard glass tubing of large bore, connected at each end with a tube filled with CaCl₂. About 2 grms. of limestone are placed in a weighed platinum boat, the latter inserted in the long tube, a gentle current of air drawn through the whole apparatus by means of an aspirator, and the boat heated gradually up to an intense heat. The tube next the aspirator should be weighed before and after the operation, and its increase in weight denotes the amount of H₂O. The apparatus

may be improved by causing the air to pass through a bottle of concentrated H_2SO_4 before entering the apparatus; and by inserting another tube full of CaCl_2 as a guard, next the aspirator. If the two weighed soda-lime U-tubes (Example No. 6, B, a) are inserted after the weighed tube, and if the boat is heated with sufficient intensity, the amount of CO_2 may be determined in the same operation.

(b). *Indirect Determination.*—Heat 2 grms. in a weighed crucible, at 130°C ., until the weight remains constant. The loss in weight denotes the amount of H_2O .

F. *Determination of Organic Matter.*—Fuse about 4 grms. of vitrified borax in a weighed platinum crucible, over a Bunsen burner, until the weight remains constant. Add about 1 gm. of limestone, weigh, and heat gradually to redness, until the contents of the crucible are in a state of calm fusion. Cool and weigh. The loss of weight denotes the $\text{CO}_2 + \text{H}_2\text{O} +$ organic matter; and by deducting the amounts of the first two, already found, the amount of organic matter is obtained.

Example No. 8.—Determination of Copper in Ores.

Duplicate samples of the same ore, finely pulverised, should always be employed in the ensuing processes, in quantities from 1 to 3 grms., according to the richness or poorness of the ore.

A. *Roasting the Ores.*—This is especially necessary when the ore contains much sulphur or bituminous matter, but is always useful in insuring its subsequent decomposition. Put about 2 grms. of ore into a porcelain capsule and heat upon a tin plate, over the flame of a Bunsen burner, carefully stirring with a platinum wire, until no more fumes are evolved. This is usually ended in about ten minutes.

B. *Extraction of the Copper.*—Three methods are commonly employed.

(a). *Mohr's Method.*—Put about 2 grms. of ore into a casserole, add 10 c.c. concentrated H_2SO_4 and 10 c.c. concentrated HNO_3 , cover with a convex cover, and heat carefully, almost to dryness, and until but slight fumes of H_2SO_4 are any longer evolved. Cool, add water, filter, and wash the siliceous residue.

(b). *Gibbs's Method for Sulphides.*—Mix the ore in a porcelain crucible with 3 to 4 times its weight of a mixture of 10 parts of KNO_3 and 14 parts of KHSO_4 . Heat the whole slowly to low redness, add enough concentrated H_2SO_4 to convert all the K_2SO_4 into bisulphate, and heat again carefully until the contents of the crucible fuse to a liquid mass. Cool, add water, filter, and wash.

(c). *Storer and Pearson's Method for Sulphides.*—Mix 2 to 5 grms. with its bulk of powdered KClO_3 in a covered beaker, add HNO_3 of ordinary strength, rather more than sufficient to cover the powder. Heat to gentle ebullition, adding from time to time KClO_3 , if needful, until the S is completely oxidised. Transfer to a casserole, add a quantity of strong HCl (rather larger than the quantity of HNO_3 first employed), evaporate to dryness, treat with water, boil, filter, and wash. It is always necessary to examine the siliceous residue on the filter for copper, before proceeding to the next process.

C. *Determination of Cu.*—Several methods may be employed, equally accurate in their results, although more skill and experience are usually necessary in the first three methods given below. Whatever method may be chosen, it is advisable for the student to render himself familiar with it, by the use of a copper solution of known strength, before applying it to the solution from the ore.

(a). *Precipitation with Zinc.*—Place the solution in a weighed platinum dish and throw in a piece of zinc, soluble in HCl without residue.* A porcelain dish, or casserole, may be substituted for the platinum, but it is best in that case to allow the zinc to rest upon a weighed slip of platinum foil. Add sufficient dilute HCl or H_2SO_4 , if necessary, to produce a moderate evolution of H_2 or,

if the latter is too brisk, add a little water. Cover the dish with a convex cover, keep up the evolution of H_2 until the solution has become colourless, and rinse off the convex cover into the dish. Test a small portion for copper with HS water, and if no brown tint is produced, ascertain if any zinc remains undissolved, by feeling about with a glass rod and by adding HCl . Press the Cu together, decant the clear liquid, and wash rapidly by decantation with boiling water until the washings are quite free from acid. Decant the water as far as practicable, rinse with strong alcohol, dry at 100°C ., and weigh. If a porcelain dish and platinum foil have been employed, transfer the foil and loose copper to a weighed porcelain crucible, dry, and weigh. Afterwards dissolve the Cu from the platinum dish, or foil, with HNO_3 , wash, and again weigh the latter.

(b). *Precipitation with Iron.*—Place the cold, dilute, and nearly neutral solution in a porcelain casserole, and insert a clean sheet of iron or flat coil of pianoforte wire. The iron must be of such a material as dissolves uniformly (without ridges), and without the separation of black particles or flakes in weighable quantity. Control the evolution of gas as in the preceding process. As soon as the iron is coated with copper, add 20 c.c. of HCl , heat almost to the boiling-point, until the solution is free from copper, remove the iron, and wash the spongy coherent mass, by decantation (being careful to prevent it from falling to pieces, and rapidly, to prevent oxidation), first with boiling water, and afterwards with strong alcohol. Transfer to a weighed porcelain crucible, dry at 100°C ., and weigh.

(c). *Precipitation with a Hypophosphite.*—The cold concentrated solution is treated with excess of a solution of an alkaline hypophosphite, and then gradually warmed on a water-bath to 80° or 90°C ., care being taken to avoid loss by a sudden effervescence. The copper shortly separates in a coherent sponge. When the precipitation is complete, wash rapidly as in the preceding methods, dry, and weigh in a weighed porcelain crucible. Collect on a filter, wash thoroughly, dry, ignite, and weigh in a close crucible as oxide.

—American Chemist.

ANALYSIS OF SUGARS.*

M. Peligot's Process.

THIS process is based on the essentially different action exercised by alkalies on the two sorts of sugars, i.e., cane sugar and glucose (*sucré d'Amidon*, grape sugar, fruit sugar, &c.). Cane sugar combines with the alkalies; it forms with bases some compounds in definite proportions from which we may extract the sugar without the latter undergoing the slightest modification. Glucose will combine with alkalies just the same, but it gives birth to some compounds of such an ephemeral nature that it is impossible to keep them intact more than for a few moments. In fact, if a solution of glucose and potash is left to itself at an ordinary temperature, we may observe that the quantity of free potash contained in the liquor diminishes every day, and finally disappears altogether when the glucose is used in excess. The glucose is transformed, in fact, into one or more acids, which colour the liquid brown, and which form with the potash some neutral salts. The action which alkalies exercise slowly on the glucose at the ordinary temperature is developed instantaneously, if the solution of these bodies is boiled; in some minutes the transformation of glucose into these acids is complete.

* Lehigh and New Jersey zinc is generally free from lead.

Saccharimétrie Optique, Chimique, et Mélasstométrique. By L'Abbé Moigno.

The alkali which M. Peligot uses in his saccharimetric analysis is lime. It is well known that pure water will only dissolve a thousandth part of its weight of lime, whilst sugar water will dissolve a considerable quantity, proportionate to the weight of sugar it contains. The compound which is formed when a solution of ordinary sugar is placed in contact with quicklime used in excess has been noted by M. Soubeiran. It is represented by the formula $2C_2H_{12}O_{12} \cdot 3CaO$.

Thus, two equivalents of sugar, weighing 427 grammes, combine with 1050 grammes of lime, or three equivalents.

To analyse a raw sugar, weigh 10 grammes of it, and dissolve it in 75 cubic centimetres of water; add little by little to this solution, which is made in a glass or porcelain mortar, 10 grammes of sifted quicklime, rub it with the pestle 8 or 10 minutes, then throw the mixture on a filter to separate the undissolved lime (this base having been used in excess). In order to dissolve rapidly all the lime the sugar will take, it is better to pass the solution a second time through the filter. By means of a graduated pipette, take 10 cubic centimetres of the solution of saccharate of lime, add to it 2 or 3 decilitres of water—add to this liquid a few drops of the blue tincture of litmus, then neutralise it exactly with a standardised solution of sulphuric acid. This proof-liquor contains per litre 21 grammes of pure sulphuric acid, with one equivalent of water. A litre of this liquid saturates the quantity of lime dissolved by 50 grammes of sugar. The normal solution of sulphuric acid is first placed in a burette graduated into cubic centimetres, each of which is divided into ten parts.

The burette is filled up to zero; then the acid is dropped into the alkaline solution, which is kept agitated during the process, until the blue tint of the latter turns red under the influence of the last drops of the proof-liquor. Then by reading the divisions of the burette, the quantity of normal acid which has been required to attain this point of saturation, you obtain the quantity of lime, and thence the quantity of sugar contained in the solution of saccharate of lime; the total volume of this solution is known by means of a table prepared by M. Payen, for estimating the volume furnished by the given weights of sugar and of water.

For the analysis of ordinary raw sugar, the above is the process. M. Peligot states that he has proved that the proportion of glucose beet sugars contain is too small to be appreciated by the second operation about to be mentioned. But it happens sometimes that granulated glucose is introduced fraudulently into raw sugars intended for refining. To prove this adulteration, as well as to analyse molasses and the inferior raw sugars, which contain variable proportions of glucose, resulting from the modification of ordinary sugar, in consequence of the processes of extraction, &c., to analyse a product containing cane sugar and glucose, the process is as follows:—

After the first alkalimetric valuation, place in a medicine phial one part of alkaline liquid, which heat in a water-bath to 212° F. for some minutes. If this liquid contains only the saccharate of lime produced by pure sugar, it becomes turbid by the action of heat, in virtue of the curious property which the calcareous compound possesses of coagulating, like the albumen of the egg, when heated to the boiling point. But this muddiness disappears on the liquid being allowed to cool, when it does not take a darker tint than it possessed before it was heated; and on submitting it to a second alkalimetric trial after it has become cool, we get the same result as before. But if the sugar contains glucose, the solution, when heated in a water-bath, takes a brown tint; a brown deposit forms, which does not disappear on cooling, if there is a large proportion of glucose, and a strong odour is developed as of burnt sugar. Lastly, the second alkalimetric determination shows a smaller quantity of lime than the first, which quantity will almost all belong to the pure sugar; the lime dissolved by the cold glucose having given birth

to some neutral salts, on which the normal sulphuric acid liquor has no action.

In cases where pure glucose is to be analysed, after the cold liquor has been mixed with the lime, the first determination will show very nearly the same extent of alkalinity as with ordinary sugar; the second, made on a portion of the liquid heated to 212° F., will indicate the same quantity of lime as that which would have been dissolved in an equal volume of pure water; this quantity is very small—one decilitre saturates four cubic centimetres of the normal solution of sulphuric acid. Although the liquor may then be brown-coloured, the point of saturation may easily be seized, by taking care to add a little more of the tincture of litmus, and to stop at the moment when the solution, which becomes green, takes a clearer tint by the addition of the sulphuric acid. The trial of saccharine solutions is made by operating as above; the only precaution necessary is to work on liquids marking 6° to 8° on Baumé's areometer.

The juices of the cane and the beet are found naturally in these conditions; if more attenuated solutions are employed, it is at the risk of not being able to dissolve rapidly all the lime which they will take up; if they are more concentrated, they become too viscid for rapid filtration. The quantity of quicklime employed for these liquids should be such that it may be very nearly equal in weight to that of the sugar which is supposed to exist in the product to be analysed. This quantity is indicated approximately by the areometrical degree of the liquor.—*The Sugar Cane.*

REDUCTION OF NITRATE OF SILVER BY CHARCOAL.

By C. F. CHANDLER, Ph.D.

WHEN solid nitrate of silver, either in crystals or sticks, is placed upon glowing charcoal, deflagration takes place, the silver being left in the metallic state, while binoxide of nitrogen and carbonic acid are evolved. The nitrate is fused by the heat of the reaction and sinks into the pores of the charcoal, and as each particle of charcoal is replaced by metallic silver, the structure of the original wood is preserved. With proper management, pieces of silver of any desired size can be prepared, showing the exact structure of the wood. A crystal of nitrate is placed on the end of a piece of charcoal, and the blowpipe flame is directed upon the coal near the crystal to start the reaction. When deflagration begins, crystal after crystal may be added. The nitrate fuses, passes down through the porous metal already reduced until it reaches the glowing coal, where it is reduced. I have prepared in this manner lumps of silver weighing an ounce or more, which exhibit most beautifully the rings of the wood.—*American Chemist.*

CORRESPONDENCE.

HISTORY OF THE AMMONIA PROCESS.

To the Editor of the Chemical News.

SIR—Dr. Angus Smith's last report, under the "Alkali Act," affords another proof that the ammonia process, originated by Chapman, Smith, and myself in 1867, has taken its place among the recognised resources of the laboratory. The time has now arrived for reviewing its history, partly with the object of getting justice done to its inventors, and partly with the object of preparing younger chemists for the sort of reception which awaits them at the hands of their chemical brethren in this country, should they be so unfortunate as to make any notable advance in chemical methods—especially in methods admitting of immediate

and practical application to such chemical questions as engage the attention of Government.

The ammonia process was published by me at the meeting of the Chemical Society held on the 20th of June, 1867; on which day I also gave evidence about it in the House of Lords, before the Royal Commission on Water Supply, and received a promise that our new method should be employed in the investigations undertaken for the Commission. The pledge was kept; the Commission received and made use of analyses done by the new process. Some of these analyses were made by my colleagues and myself at our own expense, but the greater number of them by Dr. Frankland and Dr. Odling, at the expense of the nation.

Chemists now in the habit of working the ammonia process will be amused (should they chance to turn to the blue-book containing the evidence of Drs. Frankland and Odling) to learn that these gentlemen did not get concordant results, which they attributed to some defect in the process. In 1868, many other chemists, high in official position, gave evidence before the Commissioners, and, being interrogated touching the working of our process, agreed mainly in this—That it was not a quantitative method. An honourable exception which I ought not to pass over was formed by Mr. Way, who, being in the year 1867, chemist on the Rivers' Commission, gave us his support at that early period in the history of our troubles. The last reports prepared by Mr. Way at that time contained very many water analyses done by the new process.

Very curious was the opposition we encountered at this stage of our career. One chemist could, as he informed the Chemical Section of the British Association in 1867, decompose a very dilute solution of albumen so completely, by boiling it with weak solution of carbonate of soda, as to obtain the whole of its nitrogen in the form of ammonia. Another chemist made some combustions of water residues (using a complicated apparatus for the purpose, but, as his test-analyses showed, not attaining any very unusual degree of accuracy), and wanted the Chemical Society to believe, because his combustions and our process assigned different characters to the same water, that, therefore, our process was fallacious—with combustions, confessedly tenths of a milligramme, and even a whole milligramme off the truth, he would correct, and control results claiming to be within one or two hundredths of a milligramme of the truth! One of our brethren could not work the Nessler test; another could not comprehend how we could divide organic substances so minutely as we claimed to do; another did not see how we could measure albumen quantitatively by the ammonia yielded by it, if only a definite fraction and not the entire nitrogen of the albumen were evolved as ammonia; and to this day some of our brethren have probably not been made to understand that in our first paper we described two distinct modifications of the ammonia process. But the ammonia process maintained its ground, and it is doubtful whether any new chemical method was so often and so widely practised within so short a period of its birth. I have related how from the very first the ammonia process was taken up by the two Government commissions which were sitting at the time of its invention. By-and-bye, it was adopted by the chemist to the Privy Council, the late Dr. Miller, whose latest water analyses for the Privy Council were done by our process. Almost as soon as intelligence of the method could reach the sanitary officers of our Indian Government they adopted it too. Even the Sewage Committee of the British Association used it.

J. ALFRED WANKLYN.

ELECTRICAL POWER.

To the Editor of the Chemical News.

SIR,—In the thunderstorm which about a week ago utterly shattered a tree in these gardens, there is a remarkable

illustration of the small quantity of electricity contained in a flash of lightning. The greater part of the electricity passed through an iron chair which stood under the tree. It had been newly painted green. The electricity on entering the iron reduced the metals in the paint (copper and lead) to a metallic state, at the same time fusing them. The nature of the action can scarcely be discerned by the naked eye, and probably there is not altogether half a grain of the reduced metal in the little metallic globules, which are visible by a microscope, deposited on the surface.

As the equivalent of lead is more than three times that of zinc, this is an illustration of Faraday's statement that a grain of zinc will produce more electricity in quantity than there is in a flash of lightning.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney,
June 29, 1871.

MISCELLANEOUS.

Government Prosecution of a Chemical Works.—Mr. A. E. Fletcher, Government inspector of chemical works, has entered a suit against a St. Helen's firm for an infringement of the "Alkali Act," by allowing the escape of too much muriatic acid. As the firm immediately paid the prescribed fine of £50 the case will not be proceeded with. This is the fourth prosecution instituted since the passing of the act, and they have all been directed against the proprietors of works situated in St. Helen's and Widnes.—*Liverpool Mercury*.

Patent Law Reform.—At a meeting of London Patent Agents, held on the fourth instant, to consider the proposed changes in the patent laws, George Haseltine, M.A., in the chair, the following resolutions were adopted:—(1). That the chief defects of the patent laws have arisen from a want of appreciation of the natural rights of inventors to the sole use of their inventions, an unreserved recognition of which rights must pervade every equitable patent system, and the true aim of patent legislation is to harmonise these individual rights with the material interests of the state. (2). That the grant of patents to mere "first importers" is an injustice to inventors, an injury to society, as it induces the "pirating" of inventions, and the reason for these grants no longer existing, legislation should confine the issue of patents to actual inventors and their representatives. (3). That, in view of the benefits inventors confer on the public, and the expenses incident to the completion and introduction of new inventions, a patent for fourteen years is an inadequate compensation, and we deem it expedient to grant patents for a term of twenty-one years without the privilege of extension. (4). That the patent laws impose penalties upon inventors in the form of excessive fees, which justice and public policy demand should be reduced to the amount requisite to defray the expenses of an efficient administration of a simple patent system, and fees of ten pounds for the entire term—now one hundred and seventy-five pounds—would yield more than sufficient for the purpose. (5). That the defects of the present practice should be remedied by the adoption of equitable "regulations," and the introduction of the system of granting patents, at the risk of the applicants, without any official supervision of the specification or preliminary investigation of the merits of the invention. (6). That the rights of patentees should be determined by a competent tribunal, excluding all technical objections to the validity of the patent, and we deem it expedient to dispense with jurors and "scientific experts" in patent suits. (7). That these resolutions, signed by the Chairman, be forwarded to the Parliamentary "Select Committee on Letters Patent," and such other publicity be given them as he may deem conducive to the success of a liberal measure of patent legislation.

THE

MANUFACTURE OF CHLORINE.

THE process for the Manufacture of Chlorine which bears my name is now in operation at the works of the following manufacturers, who are now making by it a very large proportion of the total chlorine produced in this country:—

Messrs. C. ALLHUSEN & SONS, Newcastle-on-Tyne.

„ BLACK & CO., South Shields.

„ J. C. GAMBLE & SONS, St. Helens.

„ GASKELL, DEACON, & CO., Widnes.

„ HALL BROTHERS & SHAW, Widnes.

The HARDSHAW BROOK CHEMICAL COMPANY, St. Helens.

Mr. WILLIAM HUNT, Castleford.

Mr. A. G. KURTZ, St. Helens.

Messrs. W. J. KANE & SON, Dublin.

„ JAMES MUSPRATT & SONS, Widnes.

Mr. MORGAN MOONEY, Dublin.

Messrs. H. L. PATTINSON & CO., Newcastle-on-Tyne.

„ W. PILKINGTON & SONS, Widnes.

„ SULLIVAN & CO., Widnes.

The WALKER ALKALI COMPANY, Newcastle-on-Tyne.

The following, though not yet actually working the process, have very nearly completed apparatus for it:—

Messrs. CHARLES TENNANT & CO., Glasgow.

„ MUSPRATT BROTHERS & HUNTLEY, Flint.

The RUNCORN SOAP & ALKALI COMPANY, Weston.

The NETHAM CHEMICAL COMPANY, Bristol.

The cost of the regeneration by my process of manganese enough for the production of a ton of bleaching-powder does not average more than about fifteen shillings; and in comparing the cost of my process with that of the old process, only a part of even this fifteen shillings has to be counted, seeing that the solution of my mud requires so much less labour and fuel than are required for the solution of native manganese. The only labour involved in the working of Weldon stills consists in opening and shutting a few cocks. One still can produce chlorine enough for from 15 to 30 tons of bleaching-powder per week, and one workman can attend to as many stills as are required for the production of the largest quantity of chlorine made by any one firm in the world.

The consumption of acid, in my process, per ton of bleaching-powder, is shown by the following figures, for which I am indebted to the courtesy of a Widnes firm. They are for the ten weeks from April 4th to June 30th, 1871, omitting Whitsun week:—

April 4th to May 30th.

Average bleaching-powder made per week ..	44 tons 1 cwt.
Average strength of the bleaching-powder } (chamber-test)	37 3/4 per cent.
Acid at 24° T. used per ton	172 cubic feet.

Week ending June 13th.

Bleaching-powder made	43 tons 11 cwt. 2 qrs.
Average chamber-test of ditto	37 23 per cent.
Acid at 24° T. per ton	166 cubic feet.

Week ending June 20th.

Bleaching-powder made	43 tons 5 cwt. 1 qr.
Average chamber-test of ditto	36 18 per cent.
Acid at 24° T. per ton	140 cubic feet.

The average consumption of acid, by the firm in question, for the ten weeks, was thus 166 cubic feet at 24° T., per ton of bleaching-powder.

The firm who have given me the above figures use Buxton lime. When an inferior kind of lime is used the consumption of acid is greater, but I believe that the average consumption, per ton of bleaching-powder, by all the firms employing my process, does not exceed 170 cubic feet at 24° Twaddell, or the quantity containing 2832 lbs. real HCl.

Although, at present, for every 2832 lbs. HCl going into their stills, few British manufacturers decompose less than 60, while many decompose 80, or even more than 80, cwt. of salt, that quantity of acid might go into the stills for every 47 or 47 1/2 cwt. of salt decomposed. In a paper presented to the Chemical Section of the British Association in 1863, by Lieut.-Colonel Allhusen and Mr. R. Calvert Clapham, it was shewn that the quantity of HCl actually condensed at the works of Messrs. Allhusen and those of the Walker Alkali Company was 55 1/8 parts per 100 parts of salt decomposed: which would give 2832 lbs. HCl per 45 cwt. and 37 lbs. of salt. There can be little doubt that that quantity of acid is nearly always condensed per 46 cwt. of salt decomposed; and I hold that, within 2 or 3 per cent, all the acid condensed might go into the stills. There are manufacturers working on the Lancashire system nearly a third of whose acid goes down their wash-towers; but there are others who do not send down their wash-towers, per ton of salt decomposed, more than the equivalent of 1 1/2 cubic feet of acid at 24° T., and what is done by these latter is of course possible for all who use close roasters. Nor need those who use open roasters have less acid for their stills, per quantity of salt decomposed, than manufacturers working on the other plan, seeing that the acid from open roasters can easily be got strong enough for a mixture of it with the pot-acid to be of quite sufficient strength for the solution of my mud.

It is perfectly possible, then, for 2832 lbs. HCl to be got into the chlorine-stills for every 47 1/2 cwt. of salt decomposed. But this quantity of acid is more than need be used per ton of bleaching-powder made by my process, as at present practised. It includes about 500 lbs. going out of the stills as free acid, and afterwards neutralized by limestone. A slight increase of still-power, permitting the stills to be worked with an excess of mud, would enable these 500 lbs. of lost acid to be reduced to 200 lbs. This would reduce the 2832 lbs. HCl to 2532 lbs., and so enable any manufacturer obtaining, in a state in which it could go into his stills, that proportion of his acid which might easily be obtained in that state by proper arrangements, to make, by the form of my process at present in use, a ton of bleaching-powder, at 37 per cent, for every 42 cwt. of salt which he decomposed.

But there is another form of my process, which is capable of yielding a ton of bleaching-powder from as little as fourteen hundredweights of salt. In this form of the process the chloride of manganese is decomposed by magnesia, instead of by lime, and the resulting chloride of magnesium is then decomposed by heat into magnesia and hydrochloric acid. The same magnesia serves over and over again continually; the loss of manganese which is inseparable from the lime form of the process is avoided; nothing is consumed but coal and air; and all the chlorine contained in the acid employed is yielded, if desired, in the free state. Bleaching-powder was successfully made by this form of the process, at the works of Messrs. J. C. GAMBLE & SONS, as far back as 1866, and at the Works of the HARDSHAW BROOK CHEMICAL COMPANY improved apparatus for it is now being prepared, and will be in operation very shortly.

Several processes for the manufacture of chlorine in which manganese is not used, the chlorine being obtained by the decomposition either of hydrochloric acid or of metallic chlorides by means of atmospheric air directly applied, are now being experimented with. Theoretically, these processes also should yield as much chlorine as the magnesia form of the manganese process, but I believe that it will be found that the reactions on which they are based can be carried to completeness only by the use of such an excess of air as to render the chlorine obtained so dilute as to require impractically large apparatus for its absorption, and hence that in practice they can be carried only so far as to make the actual yield of chlorine fall very much below that which I have every confidence that I shall soon be realizing at Hardshaw Brook; while the chlorine yielded by these processes, even when obtained by only partial decompositions, is so mixed with other gases that its absorption has as yet been effected only by causing it to travel, in apparatus of special construction, for a very long distance over exceedingly thin layers of lime. The magnesia form of my process, however, yields the chlorine in a state in which it can be employed in the ordinary chambers, and I believe that that form of my process will be found to possess so many other practical advantages as to maintain, unimpaired, the supremacy of manganese as the agent by whose means chlorine can be most conveniently and economically manufactured.

THE CHEMICAL NEWS.

VOL. XXIV. No. 607.

ON PROTOPLASMIC LIFE.

By F. CRACE CALVERT, F.R.S., &c.

A YEAR since, the publication of Dr. Tyndall's interesting paper on the abundance of germ-life in the atmosphere, and the difficulty of destroying this life, as well as other papers published by eminent men of science, suggested the inquiry if the germs existing or produced in a liquid in a state of fermentation or of putrefaction could be conveyed to a liquid susceptible of entering into these states; and although at the present time the results of this inquiry are not sufficiently complete for publication, still I have observed some facts arising out of the subject of protoplasmic life which I wish now to lay before the Royal Society.

Although prepared, by the perusal of the papers of many workers in this field, to experience difficulties in prosecuting the study, I must confess I did not calculate on encountering so many as I met, and especially those arising from the rapid development of germ-life, and of which I have hitherto seen no notice in any papers which have come under my observation. Thus, if the white of a new-laid egg be mixed with water (free from life), and exposed to the atmosphere for only fifteen minutes, in the months of August or September, it will show life in abundance. From this cause I was misled in many of my earlier experiments, not having been sufficiently careful to avoid even momentary exposure of the fluids to the atmosphere. To the want of the knowledge of this fact may be traced the erroneous conclusions arrived at by several gentlemen who had devoted their attention to the subject of spontaneous generation.

I believe that I have overcome the difficulty of the fluids under examination becoming polluted by impregnation by the protoplasmic life existing in the atmosphere, by adopting the following simple method of working.

As a pure fluid free from life, and having no chemical reaction, was essential to carrying out the investigation, I directed my attention to the preparation of pure distilled water. Having always found life in distilled water prepared by the ordinary methods, by keeping it a few days, after many trials I employed the following apparatus, which gave very satisfactory results, as it enabled me to obtain water which remained free from life for several months.

It consists of two flasks, A and B (A rather larger than B), fitted with perforated caoutchouc stoppers.* These flasks are connected by the tube D. Into the stopper of A is fitted a tube c, to which is joined a piece of caoutchouc tubing, which may be closed by the clip E. Through the stopper of B is a syphon, F, the long limb of which is cut and joined with caoutchouc tubing, which can be closed by the clip G. Through this stopper is a third tube, H, connected by caoutchouc with the tube I; this can be closed by the clip K. The tube, I, is about 3 feet long, and goes into the vessel L, which is partly filled with water.

The water to be distilled is mixed with solution of potash and permanganate of potash, and placed in the flask A.† Before distillation is commenced, a rapid current of pure hydrogen or some other gas must be

passed through the apparatus by the tube c to displace the air and carry off all the germs the air may have contained. The clip G is first left open, then this closed and the clip K opened, which allows the gas to pass through the water in the vessel L.

The gas should be passed through for about fifteen minutes. The clip E is then closed, and the distillation carried on. When the operation is complete, the gas must be again passed through the apparatus, and the connection with the tube I broken by closing the clip K. The water is drawn off through the syphon F. The long tube acts as a safety-tube, and is made so long that the absorption is noticed in ample time to close the clip before any air can enter through that tube.

The water has to be re-distilled three or four times before it is obtained free from germs, and must be kept in the apparatus in which it is distilled until wanted, to prevent any contact with air.

Some water which had been distilled on the 20th of November, 1870, being still free from life on the 7th of December, was introduced by the syphon H into twelve small tubes, and left exposed to the atmosphere for fifteen hours, when the tubes were closed. Every eight days some of the tubes were opened, and their contents examined. On the fifteenth, therefore, the first examination was made, when no life was observed; on the twenty-third two or three other tubes were examined, and again no life was detected; whilst in the series opened on the

2nd of January, 1871 (that is to say, twenty-four days from the time the tubes were closed), two or three black vibrios were found in each field.

Being impressed with the idea that this slow and limited development of protoplasmic life might be attributed to the small amount of life existing in the atmosphere at this period of the year,* a second series of experiments was commenced on the 4th of January. The distilled water in the flask being still free from life, a certain quantity of it was put into twelve small tubes, which were placed near putrid meat at a temperature of 21° to 26° C. for two hours, and then sealed. On the 10th of the same month the contents of some of the tubes were examined, when two or three small black vibrios were observed under each field. This result shows that the fluid having been placed near a source of protoplasmic life, germs had introduced themselves in two hours in sufficient quantity for life to become visible in six days instead of twenty-four. Other tubes of

* The stoppers and caoutchouc tubing used for the various joints must be new, and must be well boiled in water before use.

† The reasons why I employed permanganate of potash (in large excess) were that, under the influence of heat, its oxidising powers were much increased, and that it gave off no gas that could interfere with the purity of the water, this salt in solution not even yielding oxygen under any circumstances.

* During the intense cold of December and January last I found it took an exposure to the atmosphere of two days at a temperature of 12° C. before life appeared in solution of white of egg in the pure distilled water, whilst as the weather got warmer the time required became less.

this series were opened on the 17th of January, when a slight increase of life was noticed; but no further development appeared to take place after this date, as some examined on the 10th of March did not contain more life than those of the 17th of January.

This very limited amount of life suggested the idea that it might be due to the employment of perfectly pure water, and that the vibrios did not increase from want of the elements necessary for sustaining their life. I therefore commenced a third series of experiments. Before proceeding to describe this series, I would call attention to the fact that the water in the flask had remained perfectly free from life up to this time, a period of close on sixteen weeks.

On the 9th of February 100 fluid grains of albumen from a new-laid egg were introduced, as quickly as possible and with the greatest care, into 10 ounces of pure distilled water contained in the flask in which it had been condensed, and an atmosphere of hydrogen kept over it. On the 16th some of the fluid was taken out by means of the syphon *u*, and examined, and no life being present, twelve tubes were filled with the fluid, exposed to the air for eight hours, and closed. On the 21st the contents of some of the tubes were examined, when a few vibrios and microzyma were distinctly seen in each field. On the 27th other tubes were examined, and showed a marked increase in the amount of life. In this series life appeared in five days, and an increase in ten, instead of requiring twenty-four days, as was the case when pure water only was employed.

Albumen therefore facilitated the development of life. Of course the contents of the flask were examined at the same time, but in no instance was life detected. I believe that these three series of experiments tend to prove the fallacy of the theory of spontaneous generation; for if it were possible, why should not life have appeared in the pure distilled water, or in the albuminous solution, which were kept successively in the flask *u*, as well as in the fluids which were contained in the tubes, and had been exposed to the atmosphere or near animal matter in a state of decay, and had thus become impregnated with the germs of protoplasmic life? What gives still further interest to these experiments is, that, having operated during the severe weather of last winter, when little or no life existed in the atmosphere, I was able to impregnate the fluids with germs without introducing developed life.

The quantity of life produced in the above-recited experiments being comparatively small, I was led to infer that this might be due to the influence of the atmosphere of hydrogen employed to displace the air in the apparatus used for obtaining the water. I, therefore, on the 2nd of March, prepared a solution of albumen similar to that before employed, but expelled the air out of the apparatus by pure oxygen; and as the contents of the flask *u* were free from life on the 8th of March, a series of small tubes were filled and exposed for twenty-six hours to the atmosphere near putrid matter, and then sealed. Several of these tubes were opened on the 11th, and immediately examined, when only a few cells were observed in each field. A second lot was opened on the 14th, and they showed considerable increase of life, there being two or three vibrios under each field. A third quantity was opened on the 25th, when no increase had taken place. This latter result tends to show that although oxygen appears to favour the development of germs, still it does not appear to favour their reproduction.

As the weather had become much warmer, and a marked increase of life in the atmosphere had taken place, some of the same albumen solution as had been employed in the above experiments was left exposed in similar tubes to its influence, when a large quantity of life was rapidly developed and continued to increase. This result appears to show that the increase of life is not due to reproduction merely, but to the introduction of fresh germs; for, excepting this fresh supply, there appears to be no reason why life should increase more rapidly in the open than in the closed tubes.

In concluding this paper I have great pleasure in recognising the able and persevering attention with which my assistant, Mr. William Thompson, has carried out these experiments.

ASSAY OF GOLD AND SILVER,

AS PRACTISED AT THE LABORATORY OF THE SCHOOL OF MINES, COLUMBIA COLLEGE.

By T. M. BLOSSOM, E.M.

ALL substances containing gold and silver may, for the purpose of the assayer, be divided into two classes, as follows:—

Class I.—Minerals or ores, including incidental industrial products.

Class II.—Metallic gold and silver, and alloys, native or artificial.

GOLD.

Class I.—Minerals.

Sylvanite—Graphic Tellurium... (AuAg)₂Te₃—Au 30—Ag 10.
Nagyagite—Foliated Tellurium... (Pb,Au,Ag)₂(Te,Sb,S₂)—Au 9—Ag 0.5

Class II.—Alloys.

Native Gold AuAg—Au 65—99.
Palladium Gold Porpezite .. AuPd—Au 85.98Ag 17.
Rhodium Gold AuRh—Au 90—66.
Gold Amalgam (AuAg)₂Hg₃—Au 38.39Ag 5.
Artificial Alloys Gold Coin, Jewelry, &c.

Of the foregoing list, native gold alone occurs in nature in sufficient abundance to acquire any great commercial value. It is commonly found in a quartzose gangue, and nearly always associated with one, or more, of the following minerals: Iron and copper pyrites, mispickel or arsenical pyrites, blende, and galena.

SILVER.

Class I.—Ores and Minerals.

Mineral.	Formula.	Per cent of Silver.
1. Naumannite ..	AgSe	73.20
2. Eucairite ..	CuSe + AgSe ..	43.10
3. Hesseite ..	AgTe	62.80
4. Sylvanite ..	(AuAg)Te ₃ ..	10.00—15.00
5. Silver Glance ..	AgS	87.04
6. Stromeyerite ..	(Ag,2Cu)S ..	2.06—53.10
7. Sternbergite ..	AgS + 3FeS + FeS ₂ ..	3.420
8. Miargyrite ..	AgS, Sb ₂ S ₃ ..	36.70
9. Pyrargyrite ..	3AgS, Sb ₂ S ₃ ..	59.80
10. Proustite ..	3AgS, As ₂ S ₃ ..	65.40
11. Stephanite ..	5AgS, Sb ₂ S ₃ ..	68.50
12. Brogniardite ..	PbS, AgS, Sb ₂ S ₃ ..	26.10
13. Polybasite ..	9(Ag,2Cu)S, (Sb,As) ₂ S ₃ ..	68.00
14. Tetrahedrite ..	4(2Cu,Fe,Zn,Ag,11g)S, (Sb,As,Bi) ₂ S ₃ ..	3.09—31.29
15. Xanthoconite ..	{ 3AgS, As ₂ S ₃ + + 2(3AgS, PbS, Sb ₂ S ₃) }	64.00
16. Fireblende ..	Ag—Sb—S ..	62.30
17. Freibergite ..	5(Pb,Ag)S, 2Sb ₂ S ₃ ..	22—24
18. Kerargyrite ..	AgCl	75.33
19. Bromyrite ..	AgBr	57.40
20. Embolite ..	Ag(Cl,Br) ..	61.71
21. Iodorite ..	AgI	46.00

Minerals often containing silver in small quantities:—

1. Galena PbS.
2. Blende ZnS.
3. Pyrites FeS₂.
4. Chalcopryite Cu₂S, Fe₂S₃.
5. Erubescite 3Cu₂S, Fe₂S₃.
6. Mispickel FeS₂ + FeAs₂.
7. Altaite PbTe.
8. Nagyagite (Pb,Au,Ag)₂(Te,Sb,S₂)₂.
9. Chiviatite (Cu₂Pb)S, Bi₂S₃.
10. Dufrenoyite 2PbS, As₂S₃.
11. Enargite 3Cu₂S, As₂S₃.
12. Slags, &c.
13. Cupel Bottoms, Dross, Litharge, &c.

Class II.—Alloys.

Alloy.	Formula.	Per cent.
1. Native Silver..	AgAu (generally),	..
2. Native Gold ..	AuAg	Ag 1—35
3. Native Copper ..	Cu	sometimes 10
4. Chilenite	Ag ₆ Bi	Ag 86·2
5. Bismuth Silver ..	Ag—Cu—As—Bi	Ag 60·0
6. Discrasite { Antimo- nial Silver }	Ag ₂ Sb	Ag 78·0
7. Amalgam	AgHg ₂	Ag 35·0
"	AgHg ₃	Ag 26·0
8. Arquerite	Ag ₆ Hg	Ag 86·5
9. Artificial Alloys ..	Silver Coin, Jewelry, &c.	

The principal sources of silver are, silver glance, stéphanite, pyrargyrite, and kerargyrite, native silver, galena, and argentiferous copper ores.

The assay of gold and silver, therefore, comprises—

I. Assay of Ores, II. Assay of Alloys, according as we have presented to us material of Class I. or of Class II.

I. Assay of Ores.

Assays of gold and of silver ores are made in a manner almost precisely the same, so that a general description will answer for both, the peculiar requirements of each being pointed out in place. The assay of ores embraces the following steps:—

1. Preparation of the sample. 2. Collection of the gold and silver in a button of metallic lead. 3. Cupellation of the lead button, by which the lead is oxidised and absorbed by the cupel, leaving behind a bead of the gold and silver. 4. Weighing the bead. 5. Inquartation, parting, and cupellation of the gold residue. 6. Weighing the gold bead.

1. *Preparation of the Sample.*—It is essential, in the first place, to obtain a fair average sample of the ore, otherwise the results of the assay may be commercially worthless. Selection must be left to the judgment of the assayer. The sample must be dried, if necessary, care being taken not to roast it. It must then be pounded in an iron mortar and passed through a sieve of eighty meshes to the linear inch. If any native metal, in the form of scales or filaments, remain upon the sieve, take the weights, separately, of what has passed through and of what is left upon the sieve. The latter must be assayed according to "Assay of Alloys," and the result referred to the whole amount of ore. (See Calculation of Results.) It is essential that the whole of the sample except the malleable portion, be passed through the sieve. Mix thoroughly the sifted ore.

2. *The Collection of the Gold and Silver* in a button of metallic lead is effected in a crucible, or in a scorifier, whence two methods of assay:—

(a.) Crucible assay. (b.) Scorification assay.

The former is applicable to all ores; the latter is limited, practically, by the small size of scorifiers to the richer ores.

(a.) *Crucible assay.*—An ore of gold and silver is composed of precious metal, gangue, and oxides, sulphides, &c., of foreign metals. To collect the precious metals in a button of lead, the ore is mixed with litharge, suitable fluxes, an oxidising or a reducing agent, and fused in the crucible. Litharge is reduced to metallic lead; the latter seizes upon the precious metals and collects in a button at the bottom of the crucible, while the foreign materials form, with the fluxes, a fusible slag above the lead button. The crucible is broken when cold, and the malleable button detached from the slag by hammering on an anvil.

The following are the necessary reagents for crucible assays:—

Reagents.

Litharge.—To supply lead; to oxidise sulphur, arsenic, antimony, &c., to flux siliceous material and impurities in general.

Carbonate of Soda or of Potash.—A substitute in part for litharge, to flux siliceous and other impurities. The alkaline carbonates have the power, also, of oxidising

many metals, as iron, zinc, tin, by means of the carbonic acid they contain.

Nitre.—To oxidise sulphur, arsenic, &c.

Argol (crude bitartrate of potash).—To reduce litharge to metallic lead.

Charcoal.—A substitute for argol; also used in roasting ores, to decompose arseniates and antimonates.

Borax Glass.—To flux oxidised basic impurities, such as alumina, lime, magnesia, and oxide of iron. Borax is neither oxidising nor desulphurising.

Silica, or Powdered Glass.—Used sometimes as a substitute for borax.

Common Salt.—To cover the charge in the crucible. It also serves to wash down the sides of the crucible, if the charge boil up.

Carbonate of Ammonia.—Used in roasting ores, to decompose sulphates.

The reagents must all be finely pulverised and dried, and kept in closed vessels.

Carbonate of soda is better than carbonate of potash, because it does not deliquesce. Borax should be fused to a glass and pulverised. This prevents the loss which its boiling up might occasion, if used in the ordinary state. Litharge is an almost universal flux, and might be employed alone; but, as in this case a large amount would be required, there would be danger of losing the charge, through piercing of the crucible. Carbonate of soda is, therefore, substituted for a part of the litharge. There is an extra advantage in the use of carbonate of soda, arising from the fact that alkaline carbonates, on account of their great fusibility, can hold in suspension, without losing their fluidity, a large proportion of pulverised infusible substances.

Preliminary Assays of Reagents.

Ordinary commercial litharge always contains silver, so it becomes necessary to determine in each new lot the amount of silver contained, for deduction from the silver found in the regular assay of an ore. We must also determine, beforehand, the reducing powers of argol and charcoal, and the oxidising power of nitre. This necessity arises from the impurities of the reagents. By reducing power, we mean the amount of metallic lead that one gramme of the reagent will reduce from litharge, and by oxidising power the amount of metallic lead that one gramme of nitre will oxidise. The following are the charges for the preliminary assays:—

1.—Reducing Power.

Argol.	Charcoal.
Argol 2 grms.	Charcoal 1 grm.
Litharge 2 A. T.*	Litharge 2 A. T.
Carb. Soda .. ½ A. T.	Carb. Soda .. ½ A. T.
Salt Cover.	Salt Cover.

2.—Oxidising Power.

Nitre 3 grms.	Litharge 4 A. T.
Charcoal 1 grm.	Carb. Soda 2 A. T.
Litharge 2 A. T.	Charcoal 1 grm.
Carb. Soda .. ½ A. T.	Salt Cover.
Salt Cover.	

3.—Ag. in Litharge.

In these, as in all other cases, except when the contrary is specified; duplicate charges must be made, to afford

* Prof. Chandler has devised and adopted, in addition to the French system, a set of weights similar to that employed by the German assayers. This set includes weights designated "Assay Tons," and fractions thereof, as follows: 4 A. T., 2 A. T., 1 A. T., ½ A. T., ¼ A. T., 1-10 A. T. The assay ton weighs 29·1666 grms., and bears the same relation to a milligramme as the ton of 2000 lbs. av. bears to the troy ounce, i.e.,

$$1 \text{ milligramme} = \frac{1 \text{ (A. T.)}}{29,166} \text{ and } 1 \text{ oz. troy} = \frac{2000 \text{ (lbs. av.)}}{29,166}$$

A milligramme, then, is the assay ounce. The advantage of these weights is apparent. The ore for an assay is weighed in assay tons. Suppose that we obtain from 1 A. T. of ore 85 milligrammes, or assay ounces, of silver, we know, without calculation, that a ton of 2000 lbs. avoirdupois will yield 85 ounces troy. An article on this "New System of Assay Weights" may be found in the American supplement of the *Chemical News* for August, 1869.

some check upon the results obtained. If they differ greatly, another assay must be made; if only slightly, the mean may be taken. In the case of (1) and (2) the same precautions are necessary as in the preliminary assay of an ore. (See farther on).

All the charges require a hot fire, should be withdrawn from the furnace as soon as completely fused, and the crucibles should be tapped gently while held in the tongs, to detach any particles of lead adhering to the sides. When cold they are broken and the lead buttons are hammered into a cubical form, both because this is a convenient shape and because the buttons are thus freed from all slag. Weigh the buttons of (1) and (2) and note, in each case, the mean weight. The buttons of (1) tell us how much lead is reduced by 2 grammes of argol and by 1 gramme of charcoal. The reducing power follows. In the case of (2) we should, in the absence of nitre, have obtained a button of a certain weight, say 28 grammes, due to the charcoal present. We have obtained a button of less weight, say 13 grammes, that is, 3 grammes nitre have oxidised part of the lead, 15 grammes, whence 1 gramme nitre will oxidise 5 grammes lead. The lead button from (3) on being cupelled, will yield a bead of silver representing the amount in 4 assay tons of litharge.

In the regular assay, nitre does not act by oxidising metallic lead, but it attacks its equivalent reducing agent in the ore, be it sulphur, arsenic, or other constituent.

(To be continued).

ON THE ORIGIN OF THE DIAMOND.*

By the Rev. W. B. CLARKE, M.A., F.G.S.

CONNECTED with coal plants in transmuted deposits there has arisen another enquiry amongst ourselves as to the probable origin of the diamond. How has the diamond been produced, and to what geological formation does it belong, are questions which have had various replies. Although we may not be able to solve the mystery, it may, perchance, be not uninteresting to review the statements that have been put forth by different authorities, now the public mind in Australia is excited by accounts of increasing discoveries of the precious gem in New South Wales.

It appears that I did not miscalculate when, in 1860, I headed a notice of five diamonds that had come into my hands, "New South Wales Diamond Country" ("Southern Gold Fields," p. 272); for, up to the present time, several thousands have been brought to light. In some valuable papers by Mr. Norman Taylor, and in a report of similar character by Professor Thomson of our University, may be found a clear exposition of the phenomena presented in the diamond field at Two-mile Flat on the Cudjergong River, which these gentlemen have recently explored and described.

The opinions expressed by them are to the effect that the diamond district is limited to the presence of an ancient drift deposit covered generally by basaltic rocks, and that when found in the river bed, or in alluvial soil, the diamonds are frequently scratched and broken, whilst in the drift alluded to they are found intact. And at the points where they are thus found in the river bed, they are so found in consequence of the tailings of the miners having been washed thereto.

The river having changed its course, the area referred to is merely an alluvial space at one of those points.

The general formations of more ancient date in the vicinity are considered to be Upper Silurian traversed by greenstone, with overlying carboniferous beds as outliers of more extended strata. Mr. Norman Taylor has suggested that the diamonds have been in some way derived from the carbon in the coal measures. Opinions

as to the derivation of diamond from vegetable matter by a process of distillation, somewhat like that to which coal is due, and even from animal matter capable of supplying carbon, have been long held by certain philosophers.

Considering the facts glanced at before,* relating to the transmutation of rocks by heat and other agencies, the formation of diamond in the humid way does not appear to me an extravagant supposition. But, on examining the sand or deposit in which the Cudjergong Diamonds are found, I was struck with the amount of minute gems, such as zircon, topaz, sapphire, corundum, spinel, pleonaste, &c., which composed the finest sifted material in which gold is also found; and Mr. Norman Taylor dwells on the circumstance, that the diamond is not only associated with the gold (as in most other foreign localities), but with those gems which are held to have had an igneous origin, occurring as they do in rocks which are so denominated; and in some cases (I may add) in true lava of modern volcanos.

But before I go further into this question, I must digress, in order to explain, that though diamond is thus associated, on the Cudjergong and on the Macquarie, as at Suttor's Bar, yet there are in my knowledge hundreds of spots throughout the length and breadth of Australia where the same gems are found in as great abundance, often of much larger proportions, with or without gold and without a trace of the existence of diamond. I have found them myself in this way in a variety of places in this and the neighbouring colonies, in an area which I do not exaggerate when I call it a hundred thousand square miles; and within the last year I have received thousands of such gems from correspondents and visitors who have consulted me, without finding among them more than a few diamonds and but ten independent of the present produce from Two Mile Flat and Suttor's Bar.

Those ten were found not far from Bingera, and are the first fruits of a new locality. They were accompanied by zircon, larger than any found with diamonds on the Cudjergong, but also with very small crystallisations of the same mineral and quartz. The friend to whom I am indebted for the examination of these diamonds is encouraging a search for more. I may add that I have seen no diamond from Cudjergong exactly resembling those from Bingera.

I have received also two diamonds said to be found near Kangaloon, on the Mittagong Range; but, as many other minerals which are probably not indigenous there, have also been forwarded from the same neighbourhood, I have much hesitation in accepting the statements made.

A further announcement was made to me in 1870, of diamonds on the Darling, a few miles from Fort Bourke, but on examining a large collection of the pebbles consigned to the Commercial Banking Company as "diamonds" and "precious stones," I found that they were all varieties of silica [quartz, jasper, agate, chalcedony], with small highly polished fragments of fossil wood and other drift.

On the Cudjergong there are five principal places where the mineral is found. They occur at various depths from the surface, greenstone in some instances having caused the formation of unequal hollows for the collection of drift. The intrusive rock follows the strike of the older rocks, which is about N. 25° W.

The older drift has been since covered by a basaltic flow, which in turn has suffered from the denudation that has spread the drift, so producing a younger drift, to which Mr. Norman Taylor assigns the term Newer Pliocene, in contrast with the older. This designation is, no doubt, due to his Victorian practice. The basalt he compares with that of the Coliban River in Victoria, which from my own personal knowledge of that locality I can confirm.

The carboniferous rocks have not furnished much detritus to the older drifts; but such occurs abundantly

* From the Anniversary Address delivered to the Royal Society of New South Wales.

* "On the Transmutation of Rocks in Australasia," by the Rev. W. B. Clarke, M.A.; read before the Philosophical Society of N.S.W., May 10, 1865 (T. P. S., p. 266).

in the river bed. A still more recent wash of drift occurs on the present surface.

Mr. Taylor very properly presents to notice a difficulty which has been hinted at already.

If the diamonds were derived from the carboniferous rocks, why are they not found in the river bed, except where the tailings of the miners have been washed in? From all the evidence arrived at, the newer drift is derived from the older, and with them is associated a cement of quartz and altered rock held by a yellowish green silicate of iron and hydroxide of iron, from hand specimens of which I have myself taken gold. Mr. Taylor says it contains diamonds also.

Many of the pebbles, which are of quartz and very hard flinty altered rock, have long attracted my attention, on account of the glaze or polish which they wear. They have exactly the outward coating which distinguishes so many of the surface pebbles found in the very heart of the interior of Australia, traversed by Sturt, M'Kinlay, and Burke and Wills. What may have been the way in which these pebbles have been polished is not easy to be discovered. Iron sand, or, better still, perhaps, gem sand, in violent motion, may have been the agent, since we know granite rocks in sandy deserts are polished by sand-flows far from water. It has been suggested, that the polish arises from the action of silicated water, as the hollows in the pebbles are as smooth as the general surface. But they are only in the condition of the greatest part of the surface drift all over the interior of New Holland. Unless, therefore, we assume, that a flood of silicated water has covered the greater part of New Holland, we cannot so explain the phenomenon. If, on the other hand, the gems and the iron belong to the basaltic rocks, and if these are younger than the cement, such an explanation can only be accepted in connection with a much more distant origin for the pebbles than any local strata. The older drift, therefore, cannot have a local origin.

It is certain, moreover, that if the other gems have been derived from basaltic rocks, and not from the greenstone, of which there is no evidence, the basalt was of an older period than that which now covers the drift, and such older basalt is not traceable. All, therefore, favours the belief that the term drift, implying a driving of material from a distance, is a correct term to apply to the diamond-bearing deposits; but a question of another kind immediately suggests itself,—Was the motive power of this drift, and of necessity of the gold drifts, *fluvial* or *glacial*? A marine accumulation is not suggested; and no fossil remains, favouring such a solution of the question, have been found. Silicified wood of the carboniferous age occurs abundantly in the drift; but it must have been silicified long before any diamond could have been formed from the carbon which the original wood contained, unless diamonds claim an antiquity as high as that of the coal measures themselves, or even one higher than theirs. In that case, they must also be drifted, as well as the minerals and rocks that are associated with them.

This may be the final result of our enquiries, but there are many who (as Mr. Taylor does) think the diamond is a product of chemical forces now in operation, and therefore, it is a strictly local and limited product, not necessarily connected with any carboniferous beds of comparatively high antiquity. As magnesite exists in the vicinity, and that is certainly a recent product, arising from the decomposition of the exposed igneous rocks, so infiltration, decomposition, and reconstruction of carbonaceous materials, of whatever age, under the influence of chemical transformation, may be producing diamonds at this moment, wherever the needful conditions exist.

An author of some distinction, M. Favre, Professor of Geology at Geneva, has turned his attention to this very subject, and as his paper "On Artificial Minerals" may not be generally known, I will refer to it. [It is to be found in the *Bulletin of the Société Géologique de France*, vol. xii., 2nd series.] He therein reviews the experiments which, up to 1855, had been made in

the production of artificial diamonds, and refers to the experiments of M. Jaquelain who had procured from the diamond a carbonaceous matter having the aspect of coke, and those of M. Despretz who had proved that melted carbon and melted diamond are nothing but graphite. This is akin to the idea of Glocker of Breslau, and of others before him, that diamond is an altered coal. Petzholdt also found in different diamonds—especially the brown—traces of similar organisation to that of silicified vegetable matter; but Dufrenoy rejects the opinion of Liebig, that they can have a vegetable origin.

M. Favre shows, that of thirty-four minerals found with diamond (according to the catalogue of M. Denis), consisting of sulphurets, carbonates, oxides, silicates, and native metals, thirty have been artificially produced; and of the thirty, twenty-nine were produced by the aid of volatile chlorides.

If this be the case, though one of the conditions is heat, the argument as to an igneous origin for diamond, because it is found in association with minerals of igneous origin, must be abandoned or modified.

Ten years later, Professor Goppert, in his work "On the Organic Nature of the Diamond," pointed out, as Jaquelain had done, that it may be turned into coke. He says, that some must have been soft, as they are superficially impressed by sand and crystals; that others contain crystals of other minerals, germs of plants, and fragments of vegetation. Hence, it would certainly appear, that the origin of such diamonds cannot have been igneous, and, I may add, assuredly not more so than those granitic rocks I have already mentioned, that contain coal measure plants. He states further, in 1868, that he had a diamond which contained *dendrites*, such as occurs on minerals of aqueous origin; that there are at Berlin, one which contains bodies resembling *Protococcus pluvialis*, and another green coruscules linked together, closely resembling *Palmoglaea macrococca*. To these supposed *Algæ* the names have been given of *P. adamantinus* and *Palmogleites adamantinus*. As illustrating the views he takes of these diamonds he says, the metamorphic rocks in which they occur also contain evidences of vegetable fossils, such as *Eozoon canadense*; and that even in some topazes there are traces of organic substances.

A very interesting lecture was delivered by Dr. Percy, "On Chemical Geology," on December 12, 1863, before the School of Mines, in which he treats of the formation of silica; of "that glorious mineral corundum;" of spinel, and of other gem stones; showing the influence of water, moderate heat, and salts of chromium, and he then adds: "the diamond will come ultimately, no doubt." There is nothing to show that an igneous origin is attributed to them.

As an item in this enquiry, we may refer to a notice in *Silliman's American Journal* (vol. vi., p. 110), 1848, by Professors E. and W. B. Rogers, referring to a previous paper, on "A New Method of Determining the Carbon in Graphite" (vol. v., p. 392), in which the authors show that "the diamond may be converted into carbonic acid in the liquid way, and at a moderate heat, by the reaction of a mixture of hi-chromate of potassa and sulphuric acid, in other words, by the oxidating power of chromic acid." The method is much the same, as in the process of oxidating graphite. By this method, they obtained from half a grain of diamond an evolution of as much carbon as was nearly equal to what was due to the entire weight of the diamond.

On the other hand, Sir J. Herschel (Physical Geography) quotes the case of a Bahia diamond mentioned by Harting, which contained well-formed filaments of iron pyrites, and he infers from the combination of iron and carbon at high temperatures the possibility of an igneous origin for diamond.

A paper by Messrs. Sorby and Baker was read in 1869 before the Royal Society of London, on the structure of certain minerals, among them ruby, sapphire, and diamond, showing that these gems contain cavities entirely

or partially filled with a liquid, probably condensed carbonic acid, as well as with crystals—that some emeralds contain a strong saline solution with cubic crystals, probably of chloride of potassium, and that the black specks in diamonds (such *e. g.*, as those seen in our Cudgong mineral) are really crystals, which are sometimes surrounded by contraction cracks, a black cross appearing under polarised light. The authors conclude that the diamond does not afford positive evidence of a high temperature, though not opposed to it.

That its structure has great peculiarities has been shown by the changes produced in a yellow diamond by heat. This stone was exhibited by M. Frémy to the Académie des Sciences at Paris in 1866, when it was seen to become rose-coloured by the application of heat, returning to its proper tint on cooling. It is said to be the first instance of such a phenomenon. But, on turning to the 7th Report of the British Association, it will be seen, that in 1837, Sir David Brewster pointed out that the diamond possesses strata of different refractive powers; and he uses this as a strong argument for its vegetable origin—the changes of refraction, and, consequently, the density in parts and hardness in the same crystal being due to the action of the gases imprisoned in an expansive mass.

If we now consider the relations of the diamond to the rocks in which it is found, we shall see how great or how little is the dependence upon them for its origin.

A statement was made in *Nature*, February, 1870, p. 363, respecting the finding of a diamond in *granite* in the neighbourhood of Prague. It is described as exceeding in hardness the Brazilian diamonds. It was suggested to be zircon, but this Dlaschkowitz stone appears to be a veritable diamond. Its occurrence in *granite* was also mentioned in the *Chemical Journal*. The statement came from Professor Schafarik, who sent it to the Bohemian paper *Politik*. On such authority it was received but not believed as authentic.

It was not till I found mention of it in an Italian publication that I discovered the mistake that had been committed. In a notice, under the head "Scoperta di Diamanti in Boemia," in No. 6 of the *Bollettino of the Reale Comitato Geologico d' Italia*, published in June, 1870, p. 175, we read "Fecesi questa scoperta sul finire dello scorso anno nelle vicinanze di Dlazkovic, villaggio posto tra Bilin e Lobositz, in Boemia, dove esiste un giacimento di sabbie *Granatifere* lavorate per l'estrazione dei *piropi*, varietà di *granato* di un bel color rosso. Commista al prodotto della lavatura di queste sabbie, rimarcossi dai lavatori una piccola pietra sconosciuta, durissima, e di color giallo-verdastro, che sottoposta ad esame si riconobbe essere un piccolissimo *diamante* del peso di 57 milligrammi ed in forma di esaedro a spigoli rotundati. Dopo di quest' epoca altri *diamanti* di simil fatta si ritrovarono, benchè assai di rado in *quelle sabbie granatifere* Quantunque sia questa scoperta di ben poca importanza, pure crediamo bene di segnalare, essendo indubbiamente questo il *primo giacimento di diamantifero che in Europa si sia trovato.*"

From this we learn that these diamonds were not found in *granite*, but in a *granetiferous sand*, which is a new fact for *Europe*, but not for the supposed origin of diamond in a plutonic rock. I have quoted the original words to prevent mistakes as to the meaning.

(To be continued.)

ON THE ESTIMATION OF PHOSPHORIC ACID.

By CHARLES E. MUNROE.

I. **THOUGH** the methods commonly in use for the quantitative determination of phosphoric acid are capable in most cases of giving accurate results, yet it will, I think, hardly be claimed for them that they render new methods unnecessary, and I have therefore undertaken the

following investigation in the hope of adding something of value to our analytical resources.

My attention was first called to the employment of ferric chloride with the addition of sufficient mercuric oxide to neutralise the excess of acid. Free mercuric oxide was first added directly, but, as a complete separation could not be effected in this manner, it was found more advantageous to produce the oxide in the solution itself. This was accomplished by first adding mercuric chloride and then potassic or sodic hydrate. As sodic hydrate* can be obtained in commerce absolutely pure this was employed. The precipitate, consisting of ferric phosphate and ferric and mercuric oxides, was then evaporated to dryness in the manner recommended by Chatard,† filtered and washed on the Bunsen pump.‡ Unhappily the phosphoric acid re-dissolved after evaporation to dryness, and the process was therefore abandoned. Bunsen's delicate test with magnesium wire was used throughout the work, sometimes in connection with ammonic molybdate, for the detection of phosphoric acid.

I next studied the behaviour of aluminic oxide toward phosphoric acid, and this time met with better success.

The following course was pursued. To the boiling phosphate solution a weighed quantity of pure aluminic sulphate, previously dissolved, was added. A solution of mercuric chloride was then added, and finally sodic hydrate until a precipitate of mercuric oxide was obtained which remained undissolved. In order to hasten the operation the precipitate was allowed to settle and the supernatant liquid poured upon the filter. The gelatinous precipitate was then evaporated to complete dryness as before mentioned, filtered, ignited, and weighed. The increase of weight over that of the aluminic oxide used was phosphoric oxide. It was found extremely difficult to burn the filter. Care must be taken that for every gram. of phosphoric oxide at least 2 grms. of aluminic oxide are added.

The percentage of aluminic oxide, in the sulphate used, was determined by ignition, ammonic carbonate being used to drive off the last traces of sulphuric oxide. The following results were obtained:—

Grms.	Grms.
(1). 0.7320 $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ gave 0.1310 $\text{Al}_2\text{O}_3 = 17.89$ p. c.	
(2). 0.7100 " " " 0.1270 " " = 17.87 " "	
Mean 17.88.	

Anhydrous disodic phosphate was the first salt treated. In order to work with greater rapidity a solution of known strength was prepared of which 50 c.m.₃ corresponded to 0.6195 grms. of phosphate. This gave the following results:—

(1). 0.6195 grms. gave 0.3099 grms. $\text{P}_2\text{O}_5 = 50.02$ p. ct.	
(2). 0.6195 " " " 0.3100 " " = 50.03 " "	
(3). 0.6195 " " " 0.3097 " " = 50.01 " "	
(4). 0.6195 " " " 0.3097 " " = 50.01 " "	
Mean 50.02. Theory 50.00.	

Ammonio-sodic phosphate ($\text{Na}(\text{NH}_4)\text{HPO}_4 \cdot 4\text{H}_2\text{O}$) was next analysed. The amount of phosphoric oxide in the salt was found by igniting it and weighing the sodic metaphosphate,

Grms.	Grms.
(1). 1.4650 gave 0.6172 $\text{NaPO}_3 = 29.32$ per cent P_2O_5	
(2). 1.5017 " " " 0.6344 " " = 29.40 " "	
Mean 29.36.	

By the alumina process the following results were then obtained:—

* The article used was manufactured in England by the direct oxidation of metallic sodium.

† *American Journal of Science*, vol. iv., p. 247.

‡ A simple modification of the Bunsen pump may be obtained by connecting a piece of glass tubing, by means of rubber, with a Bunsen funnel. A funnel holding 50 c.m.³ connected with a piece of glass tubing 1 metre in length emptied itself five times, while another funnel of the same capacity, arranged as usual, did so but once. The pressure was so great that the filter had to be protected with a platinum point to prevent it from giving way.

- (1). 1'5405 grms. gave 0'4514 grms. P_2O_5 = 29'30 per cent
(2). 1'2610 " " 0'3707 " " = 29'39 "
(3). 1'1355 " " 0'3321 " " = 29'29 "
Mean 29'33.

Calcic phosphate did not give good results by this process on account of the difficulty of washing out the calcic sulphate formed. I succeeded no better with ammonio-magnesian phosphate; doubtless because some of the magnesia went down with the alumina. These experiments are sufficient to show that phosphoric acid may be determined with extreme precision in the alkaline phosphates by the method above given, but the method applies with advantage only to these salts. On the other hand, it must be remembered that many phosphates may be decomposed by fusion with the alkaline carbonates and the phosphoric acid then determined as above, so that in fact the method applies in perhaps the greater number of cases which occur in practice.

II. Rose's* method for the separation of phosphoric acid by means of mercurous nitrate and subsequent estimation in the form of pyrophosphate of magnesia has been much used. It will, however, be acknowledged that it has some serious defects. It is tedious, the many operations required increase the chances of error, and the fusion of mercurous phosphate with the mixed carbonates exerts, according to Rose, a sensible action upon the platinum crucible. Nevertheless the perfect separation which it gives is a strong recommendation of the method.

It appeared possible that a valuable modification of this process might result from the addition of mercuric oxide in the manner already employed in the alumina process above described.

The experiments were executed in the following manner. To a boiling solution of the phosphate mercurous nitrate was added in slight excess. This threw down a lemon-yellow coloured, crystalline precipitate of nitro-mercurous phosphate, which adhered to the sides of the beaker when touched by the stirring rod. Mercuric nitrate was then added and finally sodic hydrate until a slight precipitate of mercuric oxide was obtained which remained undissolved. The mixture of the two salts was found to be insoluble in both hot and cold water, and to wash like sand.

The next step was to find a readier means of treating the nitro-mercurous phosphate.

It was first proposed to dissolve the washed and dried precipitate in chlorhydric acid and titrate with potassic permanganate so as to oxidise the mercurous to the mercuric salt. This process failed. The salt was then treated with sulphuric acid. The final reaction was perfectly sharp, but the results were not satisfactory.

These results having proved that nothing was to be gained in that direction, I tried to remove the mercury by decomposing the nitro-mercurous phosphate with nitric acid and precipitating the mercury with sulphydric acid or ammoniac sulphide. The phosphoric acid was then to be determined in the filtrate by the ammonio-magnesian solution. On examining the mercurous sulphide it was found that some of the phosphoric acid was always precipitated with it. Its presence was proved by Bunsen's test with the magnesium wire. The salt was then dissolved in a solution of potassic cyanide and a current of sulphydric acid passed through, but with the same result as before. Again it was thought that the phosphoric acid might be precipitated directly from the cyanide solution by ammonio-magnesian chloride, but experiment showed that the cyanide contained so much cyanate and carbonate that, although the solution was boiled and chlorhydric acid was added to it, accurate results could not be obtained.

As the ignition of the nitro-mercurous phosphate with the non-volatile metallic oxides, in order to drive off the mercury, promised well, this process was then tried in the following manner.

The dried salt was thoroughly mixed with a weighed quantity of cupric oxide in a platinum crucible and the filter placed on top. The whole was ignited, at first gently, then to low redness, at the mouth of a muffle,* then cooled, a few drops of nitric acid added to oxidise the cupric oxide reduced by the filter, and then re-ignited. The ignition was continued until the weight became constant. The increased weight was the phosphoric oxide (P_2O_5). After ignition the cupric oxide and phosphate came out of the crucible in a beautiful coherent mass, leaving it perfectly clean and unharmed.

(To be continued).

CORRESPONDENCE.

ANALYSES OF MANURES.

To the Editor of the Chemical News.

SIR,—Mr. A. H. Church in his letter on "Agriculture and Chemistry" in the CHEMICAL NEWS for June 9, 1871, publishes an analysis of a substance sold in England as manure, and adds that the manufacturer had evidently scraped the floor a trifle too hard. I may say to Mr. Church that there are manufacturers here who do not trouble themselves to scrape the floor, but simply have recourse to the pump, when they make their "fertilisers."

I analysed a commercial manure last year which sold for 30 dollars per ton—say £5 10s. sterling—with the following result, viz:—

Water	53'5
Organic matter	21'6
Silica	1'6
Phosphate and carbonate of lime ..	23'3

100'0

It will be apparent that as 2000 lbs. of the above "dirt" contained 1070 lbs. of water the purchaser paid for the solid matters about £11 sterling, or three quarters of the price of genuine Peruvian guano.

I may add that tricks like the above have caused a widespread distrust of artificial manures.

Peruvian guano, obtained of the importers, and this is the only manure, except flour of bone, that I use in my own horticultural experiments on a small scale, maintains its old reputation pretty well, but there are rumours afloat that even this is damped more than is needful to lay the dust.—I am, &c.,

J. M. MERRICK.

Laboratory, 50, Broad Street,
Boston, Mass., U.S.

HISTORY OF THE AMMONIA PROCESS.

To the Editor of the Chemical News.

SIR,—In your last impression is a letter with the above heading from Mr. Wanklyn, in which, in the beginning of the last paragraph, speaking of the opposition which the process for estimating the nitrogenous organic matter in water, put forth by himself and Messrs. Chapman and Smith,† met with, he says, "One chemist could, as he informed the Chemical Section of the British Association in 1867, decompose a very dilute solution of albumen so completely, by boiling it with weak solution of carbonate of soda, as to obtain the whole of its nitrogen in the

* Justice is not done the muffle furnace. It gives an even, mellow heat which can be easily regulated, and for igniting precipitates it is unequalled. I have before spoken of the difficulty found in burning the filter with the aluminic phosphate. By placing it at the mouth of the muffle I was able to ignite it in the most perfect manner, without tipping the crucible, in less than ten minutes. Discretion must be used in placing the crucible in the muffle.

† Journ. Chem. Soc., vol. v., second series, p. 445 et seq.

* "Traité de Chimie Analytique," vol. ii., p. 708.

form of ammonia," and as I am the chemist referred to, I trust you will allow me to say a few words upon the matter, as I clearly think that, in the way in which Mr. Wanklyn has put it, your readers would be led to suppose that my experiments had been proved wrong by similar experiments made and published by Mr. Wanklyn or his colleagues, which has not been the case.

The paper above referred to as read by me is published in your valuable journal in full,* and, since its publication, I have repeatedly made similar experiments, and I have no reason to doubt the accuracy of the conclusions I then arrived at, both as regards the actions upon the solutions containing urea and upon the solutions of albumen described in it.

The term "*weak* solution of carbonate of soda" is not mine, but Mr. Wanklyn's; my experiments were begun with 2 grms. of dry carbonate of soda to a litre of water, as in Messrs. Wanklyn, Chapman, and Smith's experiments, but as the distillation proceeds the solution gets gradually stronger and stronger, and at the end of the experiment it may, perhaps, be considered a somewhat strong solution. The experiments are so easily made, I have just now concluded one: it was made as follows:—In 1 litre of water was dissolved equal to 0.0014 grains of dry white of egg containing 0.000217 grains of ammonia, and 2 grms. of dry carbonate of soda, and this solution was put into a retort capable of holding not less than 2 litres of water, and was rapidly distilled until the distillate did not show a trace of ammonia on standing for a quarter of an hour after adding Nessler's test. The residue in the retort, distilled with hydrate and permanganate of potash, gave a distillate which yielded only the most minute trace of colour with the Nessler test, showing that the nitrogen in the albumen was practically removed from it by the previous action of the carbonate of soda upon it.—I am, &c.,

DUGALD CAMPBELL.

7, Quality Court, Chancery Lane, London,
July 12, 1871.

MISCELLANEOUS.

Publication of Abridgments of Letters Patent.—The following letter has been received by Mr. P. Spence, of the Pendleton Alum Works, Manchester, from Her Majesty's Commissioners of Patents, in reply to an influentially signed memorial of patentees, manufacturers, and others, asking an earlier publication of the abridgments, and of the "Persons" and "Subjects" indexes, hitherto always from six to eighteen months behind. By the aid of the weekly issues referred to (and which the Commissioners kindly promise to commence on the 15th inst.), it will be perceived that any inventor, manufacturer, or other interested party, will be enabled henceforth to refer with ease and certainty to the latest patented improvements in any given field:—

"Patent Office, July 5th, 1871.

"Sir,—Your letter of May 12th and accompanying memorial were considered by the Commissioners of Patents at their meeting on the 29th ult., and I have now the pleasure to acquaint you that they decided to comply with the wishes of the memorialists. The abridgments furnished by the applicants for letters patent will therefore be published weekly with indexes of Persons and Subjects, commencing on Friday, July 15th, with the abridgments delivered between 1st and 7th of January, and of which the six months' term would expire between the 1st and 7th of July. Will you be so good as to communicate this information to the gentlemen who signed the memorial.—I am, sir, your obedient servant, B. WOODCROFT, Clerk to the Commissioners of Patents."

* CHEMICAL NEWS, vol. xvi., p. 139 *et seq.*

Meat Preserving.—Many methods have been introduced to meet the ever-growing want of England—cheap animal food. Some of these methods have been successful, and others the reverse. We could ill spare the little that is already placed at our disposal by Australian and other meat companies; and the highly remunerative character of investments in the preserved-meat trade affords a sure guarantee for greater efforts in the future than any that have hitherto been made. Liebig's process has been carried on very profitably at home as well as abroad; but the preparation of extract of meat has been declared wasteful from the small amount of stimulating material preserved, and the carting away of all albumenoid matters to the manure-heap. A new plan has been introduced by an engineer, whose experience in sugar refineries and other extensive works in hot latitudes has ensured a practical and economical solution of one of the most important problems of the day. Mr. T. F. Henley does away with steeping meat in water, and with boiling and otherwise treating it in the most costly way. He simply squeezes a definite amount of juice out of the fibre, and by mechanical desiccation preserves the latter intact. The pressed meat thus obtained contains 10 per cent of alcoholic extract and salt, and over 50 per cent of fibrin and other albumenoid constituents. It is exceedingly rich, and so is the meat-juice which Mr. Henley evaporates in vacuum pans. The juice contains about 15 per cent of alcoholic extract, and over 50 per cent of albumen. The ancient method of abstracting water only from the animal matter is relied on as the preservative, and the low temperature at which the evaporation is carried on prevents any loss of flavour or other deterioration. It is perhaps strange that so cheap and simple a process should not have been suggested before. Mr. Henley has worked at it for some time, and perfected it so as to ensure its immediate adoption. The first works, on an extensive scale, are to be opened in the River Plate, on the Estancia Nueva Alemania, where cattle have been reared and fattened for the European markets. It is proposed to slaughter three hundred bullocks daily; and since it is stated that the hides and feet pay the first cost of the bullock and of its slaughtering, the financial prospects of the undertaking wear a promising aspect.—*British Medical Journal*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 5, 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

New Method for Measuring Magnetism in Mechanical Units.—A. Cazin.—An algebraico-physical paper.

New Facts concerning Selenium.—P. Guyot.—The author draws the following conclusions from his experiments:—(1) Selenium, dissolved in sulphide of carbon, does not precipitate any other acid salts than nitrate of silver; (2) among the neutral salts, also, none but the silver salt just alluded to precipitates some metals in alkaline solution; (3) the solution alluded to precipitates some metals in alkaline solution, since there is seleniuretted hydrogen formed, which acts upon these solutions; (4) all these precipitates are seleniurets; (5) with iodine, proto-iodide of selenium in a crystalline form is obtained.

New Liquid Fire.—P. Guyot.—When to flowers of sulphur in excess bromine is added, and this mixture, after having been left

standing for a while in a glass-stoppered bottle, filtered through asbestos, there is obtained a liquid which, on analysis, was found to consist, in 100 parts, of 83.33 of bromine and 16.77 of sulphur, being, therefore, proto-bromide of sulphur. This liquid, when brought into contact with liquid ammonia, appears at first inert, but after a few minutes the mixture boils violently and bursts into flame. The author describes at length his experiments which led to the following results:—Bromide of sulphur behaves in the presence of ammonia like chloride of sulphur, but the reaction with the bromide is not instantaneous; the bromide of sulphur may be employed for the purpose of producing liquid fire, to which the author gives the name of *nouveau feu loirain*. The reader is reminded that, in 1869, the late J. Nicklès, at Nancy, discovered a composition for a liquid fire which obtained the name of *feu loirain*. The use of the bromide of sulphur is more safe, but all attempts made by the author to bring this mixture, by various means, into a more manageable pasty mass have failed.

Dynamite.—P. Guyot.—The main gist of this paper is the communication of an observation which is not by any means unimportant. The substance known as dynamite (consisting essentially of nitroglycerine absorbed by any suitable inert powder) is met with in the trade made up in cartridges weighing, on an average, 71 grms., and packed in boxes weighing, with contents, about from 25 to 30 kilos. The author, happening to have in his possession a number of cartridges containing dynamite (the body of the cartridge is made of stout grey paper), found that these objects, after some lapse of time, became moist and oily looking, and a cardboard box in which the cartridges were kept was also found impregnated with a liquid, which, on investigation, turned out to be nitroglycerine. A small piece of the paper so impregnated exploded violently when brought into contact with glowing coals, and the like effect was observed when a piece of the paper was laid upon an anvil and smartly struck with a hammer. The author also found that the wood of the boxes in which dynamite cartridges are kept becomes, by slow degrees, impregnated with nitroglycerine, and thereby a most dangerously explosive material, which may give rise to serious accidents in warehouses where dynamite is kept.

June 12, 1871.

This number contains the following original papers and memoirs bearing upon chemistry and allied sciences:—

Memoir on the Celestial Origin of Atmospheric Electricity.—M. Becquerel.—This very lengthy essay is, notwithstanding its high intrinsic value, not well suited for any useful abstraction, an observation which also applies to the two following papers.

Note on Simple Relations Existing between the Pressure of Aqueous Vapour and the Temperature.—J. G. Duperray.

Physical Constitution of the Sun.—A. Boillot.

Establishment of a Meteorological Observatory on the Azores.—Dr. Buys-Ballot.—After briefly pointing out the great importance, not simply in a scientific, but also in a mercantile and industrial point of view, of having, on one of the islands just named (they belong to Portugal, and are situated at about 40° N. lat., and 30° W. of Greenwich), a meteorological station, connected by submarine telegraphs with Europe and America. The author states that probably by September, 1872, this desirable object will be accomplished by the activity of M. Pradesso da Silveira, the Director of the Observatory at Lisbon.

June 19, 1871.

This number contains the following original papers and memoirs relating to physico-chemical sciences:—

Low Temperature of the 18th of May last and of the first days of June.—Ch. Sainte-Claire Deville.—From the contents of this lengthy paper, containing a series of communications received by the author from different localities in France, it appears that, even in the very south of that country, the temperature fell during this period to so low a degree as has not been witnessed within man's memory at this time of the season; moreover, heavy storms, accompanied by deluging rains and seriously destructive hail, have occurred in many parts of France; while near Paris, at St. Germain en Laye, the author found the temperature was -3.5° on the 18th of May, in the morning, at a height of 33 centimetres above the soil (a meadow).

Alteration which the Yellow Metal employed for Coppering (as it is technically termed) Wooden Ships undergoes, and on the means of ascertaining the nature thereof beforehand.—A. Boiner.—After referring to his former labours on this subject (see *Ann. de Chim. et de Phys.*, 4th series, vol. xv.), the author in this memoir states chiefly that the effects of wear and tear (slow dissolving of the metal by the aid of an electric current) are only applicable under the following restrictions:—The alloy to be tested should be previously acted upon by an acid (*décapé*); a chemical analysis of the alloy is also necessary in order to ascertain its precise composition, and for the purpose of ascertaining the impurities it may contain. Lastly, it is necessary to know whether or not the metal was rolled out while red-hot.

Dissociation as Viewed Thermodynamically.—J. Moutier.

Heat Produced by the Combustion of Magnesium and Zinc.—A. Ditte.—Are both algebraico-physical memoirs.

Researches on the Formation of Gallic Acid.—M. Sacc.—The author points out that, if the theory usually accepted for the mode of formation of gallic acid (which, according to Pelouze's experiments, has the formula $C_6H_3O_5$, and is derived from tannic acid simply by its splitting up into sugar and gallic acid in the presence of water) be correct, there ought to be obtained a smaller quantity, by weight, of gallic acid from a given quantity of tannic acid used. That this does not so happen has been proved already by Dr. Stenhouse, who found

that tannic acid, while being converted into gallic acid, yields its own weight of the latter. The author of this paper, having made a series of experiments on this subject, found that tannic acid, while being converted into gallic acid, increases considerably in weight, and concludes that hydration there takes place, and that accordingly tannic acid is only the anhydride of gallic acid.

Use of Gaize for the Preparation of Alkaline Silicates.—A. Scheurer-Kestner.—After referring to the memoir on gaize (a peculiar mineral found in some parts of France), by Sainte-Claire Deville and Desnoyer (see *Comptes Rendus*, vol. lxx., p. 581), the author communicates, at length, a series of experiments instituted by him with a gaize, composed, in 100 parts, of—Hygroscopic water, 3.4; water of combination, 3.2; silica soluble in alkaline solutions, 43.7; insoluble silica, 40.8; alumina, 3.8; ferric oxide, 3.8; lime, 0.9. The results of the author's experiments are that gaize, boiled for a length of time with caustic soda, yields a silicate, $Si_2Na_2H_2O_{10}$; that boiling under pressure at 150° does not yield a better result, and that therefore it is not likely that gaize may be industrially employed for the preparation of alkaline silicates by being simply boiled with caustic soda.

Use of Dynamite for the Purpose of Breaking Up Heavy Masses of Cast-Iron.—P. Champion.—This paper records, at considerable length, the results of some experiments made upon an anvil belonging to a steam hammer, and weighing over 5 tons, which was broken up into lumps of suitable size for the purpose of being smelted down by the aid of two small charges of dynamite.

Experimental Researches on the Constitution of Blood and on the Nutrition of Muscular Tissue.—W. Marcat.

This number contains, also, a series of papers bearing upon meteorology.

Revue des Cours Scientifiques de la France et de l'Etranger, (2nd series), No. 1, July 1, 1871.

This number does not contain any original papers relating to chemistry and allied sciences.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 10, 1871.

This number contains the following original papers and memoirs:—

Density (Sp. Gr.) of the Elements Compared with the Density of their Oxides.—H. Ludwig.—In order to give some idea of the main contents of this lengthy paper, we quote the following examples from its contents:—Light elements—viz., those the oxides of which are heavier than the elements themselves—Hydrogenium, solid, sp. gr. 0.733 (T. Graham), water, sp. gr. 1.000; silicium, sp. gr. at 10°, 2.49 (F. Wöhler), silica, sp. gr. at 4°, 2.652 (Dumas and Lecoyer); the oxides of these elements exhibit neither an acid nor alkaline reaction, and consequently correspond in that respect with those of the earthy metals. Potassium, sp. gr. 0.865 (Gay Lussac and Thénard); potassa, sp. gr. 2.656 (Karsten). In this manner twenty elements are named and proved to belong to the class of light elements. The opposite class, heavy elements, contains, according to the author, oxygen, the haloids, selenium, sulphur, nitrogen, &c., forty-one in number.

Observations on the Constitution of Rosaniline.—H. Baumbauer.—The value of the contents of this paper depends upon the diagrams representing the constitutional formula of rosaniline, first as represented by Dr. Kekulé in his work "Chemie der Benzol Derivate," vol. i., p. 180, and next as modified by this author.

Contribution to our Knowledge on the Constitution of the Allyl Compounds.—F. Geromont.—The author states that, starting from the proposition that the constitutional formula of allyl-bromide (*allyl-bromür*) should be—

he succeeded in preparing from allyl-bromide, by the addition thereto of hydrobromic acid, two other compounds, of the following constitution:—

This reaction takes place readily when concentrated hydrobromic acid is used, and the operation performed in sealed tubes. At 100°, the two bodies the formula of which has just been quoted are separated from each other by fractioned distillation. The trimethylen-bromide forms about two-thirds of the entire crude fluid first obtained; after

having been purified, the sp. gr. of this body was found to be, at 0° , 2.0177; its boiling-point, 160° — 163° . By the action of acetate of silver, aided by glacial acetic acid, the trimethylen-bromide is converted into acetic acid-trimethylenester (*essigsäure-trimethylenester*), a colourless heavy liquid, boiling at from 203° to 205° , and yielding, on being saponified with hydrate of baryta, trimethylen-glycol.

On Umbelliferon.—H. Hlasiwetz. The substance was just named was first discovered by Zwenger and Sommer (*Ann. Chem. Pharm.*, vol. cxxxix, p. 99) in the bark of *Daphne mezereum*, and was next found by them in the products of the dry distillation of several resins derived from plants belonging to the natural order of the *Umbelliferae*, umbelliferon being best obtained from the galbanum resin. The main portion of this essay is devoted, however, to a discussion bearing upon the constitutional formula of umbelliferon in reference to the recent researches on *asculetin* (*CHEMICAL NEWS*, vol. xxiii., p. 275) by H. Schiff. Taking into consideration the behaviour of umbelliferon to acetyl-chloride, the author of this paper gives, for the body just alluded to, and *asculetin* and *para-asculetin*, the following formulae:—

When an alkaline solution of umbelliferon is treated with sodium-amalgam, there is obtained umbelic acid, $\text{C}_8\text{H}_{10}\text{O}_3$, which is readily converted into resorcin, which is also directly formed from umbelliferon by the action of strong caustic potassa solution upon that body at a higher temperature.

Researches on the Constitution of the Benzol Derivatives.—V. von Richter.—This is the second instalment of an essay on this subject. According to this author, the three isomeric series of the benzol derivatives may be represented as follows:—

New Class of Dyes.—A. Baeyer.—The author first refers to his former paper on gallein (*CHEMICAL NEWS*, vol. xxiii., p. 275). The composition of this substance was, on analysis, found to be $\text{C}_{18}\text{H}_{14}\text{O}_7$. When treated with zinc and dilute sulphuric acid, gallein is converted into gallin, a solid, colourless, crystalline substance, soluble in ether, and, better yet, in an aqueous solution of pyrogallol acid. Gallin, dried in vacuum, was found, on analysis, to lead to the formula $\text{C}_{18}\text{H}_{16}\text{O}_6$; it is difficultly soluble in cold, but readily soluble in boiling water, and very readily in alcohol. Gallin exhibits great similarity to hæmatoxilin, with which it also shares the property of becoming readily pink-coloured, both in solid state and in solution; it (gallin) dyes tissues in the same manner as gallein. When this last-named body is treated with concentrated sulphuric acid at 200° , cöruleine is obtained, the formula of which is $\text{C}_{18}\text{H}_{10}\text{O}_8$, its mode of derivation from gallein being expressed by—

Cöruleine is difficultly soluble (almost insoluble) in water, alcohol, and ether; it dissolves more readily in acetic acid, yielding a dirty green-coloured solution. In hot aniline it is readily soluble, the solution exhibiting a magnificent indigo-blue colour; this solution, slightly acidified with acetic acid, dyes wool indigo-blue. Cöruleine dissolves in alkaline solutions, exhibiting a beautiful green colour; tissues mordanted with alumina are dyed green by this solution, while, if mordanted with iron compounds, a brown colour is the result. These dyes are fast, and resist soapduds. The author points out that there is a great similarity between cöruleine and the lo-kao, Chinese green. By the aid of reducing agents, cöruleine is converted into curilin, soluble in ether, and yielding a yellow-coloured solution. By the action of phthalic acid anhydride upon resorcin, fluoresceine is formed, a yellowish-red coloured body, soluble in alcohol; this substance dyes silk and wool yellow without the aid of any mordant. When fluoresceine is heated with reducing agents, it is converted into fluorescein, which, on being treated with chromic acid, becomes again fluoresceine.

Action of Hydriodic Acid upon Hydrophthalic Acid.—K. Mizerski.—When hydrophthalic acid is submitted, along with hydriodic acid, in a sealed tube, to a temperature of from 240° to 250° for about six hours, the main product of this reaction (about 60–65 per cent) is found to be hexa-hydrophthalic acid, $\text{C}_8\text{H}_{12}\text{O}_4$, exactly identical with the substance obtained by Dr. A. Baeyer from tetra-hydrophthalic acid, agreeing therewith also as regards its melting-point (207°).

Les Mondes, June 29, 1871.

This number does not contain any original papers relating to chemistry and collateral sciences; but we meet herein with a short scientific-biographical notice on—

The Late Professor Payen.—P. Thomas.—The author, the nephew of the deceased, states that the eminent *savant* died lately of apoplexy. As regards the very varied and immense mass of re-

searches and discoveries made by the deceased, the following brief instances are quoted:—In 1824, he was the first who pointed out the rational method of applying manures in agriculture, and about the same time brought forward the theory of the decolouration of liquids by animal charcoal, also suggesting the use of the residues of the sugar refining (scums) which contain more or less animal charcoal along with other substances) in agriculture. In 1830, he laid the foundation of the proper valuation of manures according to their richness in nitrogen. The late author's exhaustive researches on amylaceous matter settled the exact structure, mode of formation, and the derivation of dextrine and glucose from starch; the existence of diastase, also, was first pointed out by the deceased. Prof. Payen, very well known, also, among a great many others, by his excellent work on industrial chemistry, "*Précis de Chimie Industrielle*" (Paris: Hachette and Co., 1867), was, since 1842, a member of the French Academy of Sciences, and held the Professorships of Industrial Chemistry at the Ecole Centrale des Arts et des Manufactures since 1830, and at the Conservatoire des Arts et Métiers since 1839. The deceased was not only a very eminent scientific man, but was thoroughly and practically acquainted with almost every branch of industrial pursuits. Anselme Payen was born at Paris on January 17th, 1795, and was in early life first the technical manager of a beet-root sugar work at Vaugrard, and afterwards of a very large chemical work near Paris.

July 6, 1871.

Among the great variety of matter contained in this number, including political subjects, the only original communication which belongs to chemico-physical science is—

University of Cordova, Argentine Republic, South America.—The Government of the country alluded to has just added to its University (hitherto only consisting of two faculties—viz., law and divinity) a faculty of sciences, of which Dr. Burmeister, the celebrated author of the work bearing title "*Geschichte der Schöpfung*," and hitherto Director of the Museum at Buenos Ayres, has been appointed the Dean, while the following gentlemen have been appointed to the chairs placed after their names:—Dr. Stelzner, mineralogy and geology; Siewert (from Halle), chemistry; Lorenz (from Munich), botany; Holzmueller (from Merseburg), mathematics; Gould (from the United States), astronomy. For the chairs of natural philosophy and zoology, it is also expected to find amongst the scientific men of Germany gentlemen who will be willing to take these positions. The Argentine Republic has a superficial area of 515,000 English square miles, with barely 2,000,000 inhabitants. Cordova is a city with 25,000 inhabitants, and is rather centrally situated.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 5, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Adulteration of Roasted Chicory with Pulverised Peat.—Dr. Th. Swartz.—After referring to the circumstances which caused this investigation, the author states that his process for the detection of this gross fraud, though not injurious to health, is based upon the following points:—Since peat is a fossil combustible, due to the spontaneous decomposition of woody matter, and since among these products are found hydrocarbons belonging to the germs petroleum, ozokerite, paraffin, fossil wax, &c., these substances have been searched for by the author among peat. This, having been treated with chloroform, yields from 4 to 5 per cent of a bituminous matter, which, after having been purified, presents unmistakable characters. Chicory, not adulterated with peat, does not, of course, yield any similar substance. Peat, being in a great measure produced by partly-decayed plants, remnants of *Sphagnum*, *Hypnum*, and *Deschampsia* may be discovered among chicory adulterated with peat by the aid of the microscope. Peat yields, on average, from 8 to 10 per cent of ash, and if of very old formation, even as much as 20 per cent; while chicory does not, in its natural, pure, unadulterated state, yield more than from 4 to 6 per cent of ash, provided, previous to roasting, the roots have been well cleaned and freed from adhering sand and soil. To this paper is added an excellently executed number of engravings representing the microscopic structure of the plants above alluded to, and also that exhibited by pure chicory.

Preservation of Meat.—Dr. Melsens.—Samples of meat preserved in contact with air for a period of more than two years, were exhibited at the meeting of this Academy by the author, who, however, did not explain anything concerning the process whereby this result was obtained; but to the samples were added affidavits from competent judges—among whom were veterinary surgeons and the sanitary veterinary inspector of the abattoirs at Bruxelles—confirming the facts and certifying to the good quality of the meat after having been kept for so long a period of time.

The other papers in this number relate to botany and palæontology.

Journal für Gasbeleuchtung und Wasserversorgung, No. 10, 1871.

In addition to a series of very important papers directly bearing upon gas and waterworks' engineering and management, this number contains the following matter relating to chemistry:—

Influence the Water Supplied to Dantzic has on Lead Pipes.—Dr. Lissauer.—After referring to some subjects only of local interest, the author states that it may be taken as a general rule that,

with soft water, leaden pipes, during the first four or five weeks after having been laid on, contaminate such water with lead, but afterwards, a strongly adhering coating of oxide of lead having been formed inside the pipes, no further danger is to be apprehended. As soon as water contains 58 milligrams. of carbonate of lime per litre, kept in solution by carbonic acid, leaden pipes are not acted upon.

Method of Improving Spring Water.—Dr. Schilling.—The sides and bottom of the well should be made perfectly watertight by means of masonry. Into the bottom wall is to be inserted a glazed earthenware tube or pipe, some feet in length, care being taken to cement it watertight into the bottom masonry; this tube should be filled, first with a layer of clean pebbles, next a layer of coarsely granulated charcoal, and next a layer of fine, white, clean sand, or other suitable filtering materials, through which the water of the well is forced to pass upwards, being thereby purified. The author states that the cleansing, renewing, of the filtering materials will have to be occasionally attended to; but it is clear that this operation, supposing the well to give, as desired, a constant and large supply of water, cannot be easily brought into actual practice.

Zeitschrift für Chemie von Beilstein, No. 7, 1871.

This number contains the following original papers and memoirs:—

Action of Chlorine upon Ethyl-Chloride.—W. Stadel.—This paper contains the abstract of an account of a series of experiments on the chlorine substitution products of ethyl-chloride made and published by the author some years ago, care having been taken to arrange the conditions of the experiments in such a manner as to obtain only the lower chlorinated products. The main contents of this paper bear upon the differences of results obtained by the author and by other experimenters on this same subject, and relate chiefly to the boiling-points of some of the substances obtained.

On Para-Sulpho Benzoic Acid.—I. Remsen.—After briefly referring to his researches on para-oxybenzoic acid (*CHEMICAL NEWS*, vol. xxii., p. 228), the author, in this paper, gives an account of some researches made in order to verify the correctness of his view that crude sulpho-benzoate of potassium contains two isomeric salts. For this purpose, the acid of that salt was set free, and next combined with baryta. This compound was repeatedly purified and re-crystallised; it lost its water of crystallisation at from 250° to 260°. The analysis of the salt led to the formula $(C_6H_4S_2O_6)Ba + 3H_2O$. The mother-liquor of the crystals of the salt just alluded to yielded another baryta salt of a different crystalline structure. Both of the salts here spoken of, having been converted again into potassium salts, the author found that the first-mentioned baryta salt yielded, on being fused with caustic potassa, pure para-oxybenzoic acid, accordingly proving that the baryta salt, the formula of which is above mentioned, is a salt of para-sulpho benzoic acid. Acid para-sulpho benzoate of barium is very difficultly soluble in hot water; it crystallises immediately on cooling. The neutral potassa salt of this acid is readily soluble in hot as well as in cold water; the chief product of the action of sulphuric acid upon benzoic acid is, therefore, meta-sulphobenzoic acid, while some para-sulphobenzoic acid is also formed.

On Oilbanum.—A. Kurbatow.—The author first refers to the researches on this subject made by Dr. Sterner (*Ann. Chem. Pharm.*, 35, 306 (1870)). According to these experiments, oilbanum consists of resin, gum, and an ethereal oil having the formula $C_{28}H_{42}O$. The author of this paper, having repeated Dr. S.'s researches, found that the ethereal oil of encens, boiling at 162°, yields, when submitted to fractionated distillation, an oil not containing oxygen (the crude oil contains that element) boiling at 160°, and another oil which boils at 175°, and contains oxygen. The first-named body—the main bulk of the oil—is termed by the author oilben, $C_{16}H_{10}$, (sp. gr. at 12°, 0.863); it is soluble in alcohol and ether, and is resinified by nitric acid: the other portion, which boils at 175°, contains, perceptibly—C, 83.55; H, 5.57; reit upon 100 being O; does not yield, when treated with sodium, any hydrocarbon. Oilben absorbs, while becoming brown-coloured, hydrochloric acid gas, and yields a camphor-like solid substance which fuses at 127°. Formula, $C_{10}H_{10}.HCl$. The resinous matter contained in the encens, previously deprived of its essential oil, is soluble in alcohol, brown-coloured, brittle, very readily fusible; it contains, in addition to oxygen, upon 100 parts, C, 76.96; H, 10.97. The resin submitted to distillation yields chiefly a compound, $C_{10}H_{10}$.

Dinitro-Aniline.—W. Rudnew.—The author describes, in catalogical order, and briefly: Nitro-acetanilid, $C_6H_5(NO_2).NH(C_2H_5O)$, soluble in boiling water and cold alcohol, fuses at 120°, crystalline; dinitro-aniline, $C_6H_3(NO_2)_2.NH_2$, a greenish-yellow coloured powder, insoluble in cold and boiling hot water, tolerably well soluble in boiling alcohol, fuses at 175°; dinitro-citraconanil, $C_6H_3(NO_2)_2.N(C_4H_9O_2)$, not at all soluble in water and not in cold alcohol, readily so in that liquid when boiling, crystalline, fusing at 120°.

Action of Water upon Chloride of Antimony.—A. Sabanijen.—This paper treats mainly on the composition of the so-called algaroth powder, oxychloride of antimony, and on the mode of its formation, and the influence of time and temperature thereupon. The oxychloride here alluded to, $Sb_2Cl_3O_5$, is a crystalline material obtained, as is well known, by adding water to chloride of antimony, if cold be taken 30 times the bulk of the chloride, if hot 3 times, care being taken to keep the liquid at about 65° for several hours after the addition of the water to the chloride.

Volumetrical Estimation of Copper in Brass.—M. Kirpitschow.—The main results of the researches recorded in this paper may be summarised as follows:—The titration of an ammoniacal solution of brass with Na_2S is equally correct as if copper alone were present. A little more Na_2S (0.3 c.c.) is required than with pure copper, but this quantity is a constant one, amounting to about 1.5 per

cent, and does not depend on the quantity of zinc which is present, since that metal is not acted upon by the Na_2S until after the precipitation of all the copper.

Isomeric Dibromtoluols.—E. Wroblevsky.

Some of the Conversions of Isomeric Bromtoluolines.—E. Wroblevsky.—This and the preceding paper are, as regards their contents, papers recording, in catalogical order, a series of names and formulae of bodies not well suited for any useful abstraction.

Mono- and Dinitro-Naphthalene.—Drs. F. Beilstein and A. Kuhlberg.—Mono-nitro-naphthalene, prepared by the action of strong crude nitric acid upon naphthalene, is readily soluble in sulphide of carbon, difficultly in alcohol, crystalline, and fuses at 58.5°. Nitro-amido-naphthalene, $C_{10}H_7(NO_2)(NH_2)$, the sulphate of this base, $[C_{10}H_7(NO_2)(NH_2)]_2SO_4 + 2H_2O$, is difficultly soluble in cold water, and loses its water of crystallisation by standing over sulphuric acid under a bell-jar; the free base, $C_{10}H_7(NO_2)(NH_2)$, is a red-coloured crystalline body, fusing at 118°. The authors conclude, from their experiments, that—(1) Naphthalene behaves in a manner analogous to benzol; and (2) that in the *a* dinitro-naphthalene the two nitro-groups are symmetrically placed. A dinitro-naphthalene is not acted upon by a concentrated and hot mixture of sulphuric acid and bichromate of potassa.

TO CORRESPONDENTS.

* * Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxiv. commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

Alkali.—A table for the percentage estimation of the carbonate of calcium contained in animal charcoal, calculated from the volume of the carbonic acid, will be found in "Select Methods in Chemical Analysis," by W. Crookes, F.R.S. (Longmans). We know of no other published tables connected with Dr. Schiebler's calcimeter.

S. E. Phillips.—We do not remember the dates. Consult the Index from vol. xx.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

Royal Institution of Great Britain, Albemarle Street, W.

The next ACTONIAN PRIZE, or PRIZES, will be awarded in the year 1872 to an Essay, or Essays, illustrative of the Wisdom and Beneficence of the Almighty.

The subject is "The Theory of the Evolution of Living Things." The Prize Fund is Two Hundred Guineas, and it will be awarded as a single Prize, or in sums of not less than One Hundred Guineas each, or withheld altogether, as the Managers in their judgment shall think proper.

Competitors for the Prize are requested to send their Essays to the Royal Institution on or before June 30th, 1872, addressed to the Secretary; and the adjudication will be made by the Managers in December, 1872.

H. BENCE JONES, Hon. Sec. R.I.

July, 1871.

St. George's Hospital Medical School.—A Gentleman is required as TEACHER of PHYSIOLOGICAL CHEMISTRY. He will have to give, during the Winter Session, a Course of Fifteen Practical Demonstrations upon the Chemical Composition and Analysis of the Tissues and Secretions.

This course will have to be repeated more than once to different Classes of Students, so that it may probably occupy one hour of his time three days a week during the whole of the Winter Session. Laboratory accommodation will be found, and the remuneration will be about £40 a session.

Applications to be addressed to

WILLIAM WADHAM, M.D., Dean of the School.

St. George's Hospital,

July 11, 1871.

NEW EDITION OF CULLEY'S TELEGRAPHY.

In One Volume, 8vo., with over 120 Woodcuts and 4 Plates of Machinery and Apparatus, price 14s. cloth.

A Handbook of Practical Telegraphy. By R. S. CULLEY, Member Inst. C.E., Engineer-in-Chief of Telegraphs to the Post Office. The Fifth Edition, revised and enlarged.

London: Longmans, Green, and Co., Paternoster Row.

Royal 8vo., pp. 388, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling,

A Concise View of the Law connected with Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentees' Manual."

London: Longmans, Green and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitric Gunpowder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.— EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College. The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under 4 per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under 4 per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

Methylated Spirits.— David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

W. NEILL & SON'S PATENT BLOWING ENGINES, ACID PUMPS, AND DONKEY PUMPS, ESPECIALLY ADAPTED FOR WELDON'S PATENT CHLORINE PROCESS.

W. NEILL and SON have just Patented most important improvements in the Air-Valves of Blowing-Engines, which enable them to secure the most perfect "Cut-off" at the termination of each stroke, together with a perfectly free inlet and outlet for the Air at the proper time, thus securing a much better result from each stroke of the Air-Piston, with greater freedom of action, also a very great saving in the wear and tear of valves.

These improvements are of especial advantage to Engines working under the comparatively high pressure of blast required in the Weldon Process.

W. Neill and Son have supplied Blowing Engines and Pumps to all the principal Alkali Makers who have adopted the Weldon Process, and are ready to furnish Plans and Estimates for the erection (with the latest improvements) of the whole of the Plant required.

Efficiency and Simplicity of Construction, with the best workmanship, guaranteed. References on application.

W. NEILL and SON, ENGINEERS, &c.,
BOLD, ST. HELEN'S JUNCTION, LANCASHIRE.

HORSELEY FIELDS CHEMICAL WORKS,
WOLVERHAMPTON.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA OF HONOUR, being the First Prize, and superior to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar, Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

THE CHEMICAL NEWS.

VOL. XXIV. No. 608.

ON DUST AND SMOKE.*

By JOHN TYNDALL, LL.D., F.R.S.,
Professor of Natural Philosophy, Royal Institution.

AFTER a few preliminary experiments illustrative of the polarisation of light, Professor Tyndall adverted to the polarisation of light by fine dust, by the sky, and by the coarser particles of smoke. In the former the direction of maximum polarisation, as in the case of the sky, is at right angles to the illuminating beam. In the latter, according to the observations of Govi, the maximum quantity of polarised light was discharged obliquely to the beam. Govi's observation of a neutral point in such beam, on one side of which the polarisation was positive and on the other side negative, was also referred to. The additional fact was then adduced that the position of the neutral point varied with the density of the smoke. Beginning, for example, with an atmosphere thickened by the dense fumes of incense, resin, or gunpowder, and observing the neutral point, its direction was first observed to be inclined to the beam *towards* the source of illumination. Opening the windows so as to allow the smoke to escape gradually, the neutral point moved down the beam, passed the end of a normal drawn to the beam from the eye, and gradually moved forward several feet down the beam. The speaker did not halt at these observations; they were introduced as the starting-point of inquiries of a different nature, and after their introduction the discourse proceeded thus:—

But what, you may ask, is the practical good of these curiosities? And if you so ask, my object is in some senses gained, for I intended to provoke this question. I confess that if we exclude the interest attached to the observation of new facts, and the enhancement of that interest through the knowledge that bye-and-bye the facts will become the exponents of laws, these curiosities are in themselves worth nothing. They will not enable us to add to our stock of food, or drink, or clothes, or jewellery. But though thus shorn of all usefulness in themselves, they may, by leading the mind into places which it would not otherwise have entered, become the antecedents of practical consequences. In looking, for example, at this illuminated dust, we may ask ourselves what it is. How does it act, not upon a beam of light, but upon our own lungs and stomachs? The question at once assumes a practical character. We find on examination that this dust is organic matter—in part living, in part dead. There are among it particles of ground straw, torn rags, smoke, the pollen of flowers, the spores of fungi, and the germs of other things. But what have they to do with the animal economy? Let me give you an illustration to which my attention has been lately drawn by Mr. George Henry Leves, who writes to me thus:—

"I wish to direct your attention to the experiments of Von Recklingshausen should you happen not to know them. They are striking confirmations of what you say of dust and disease. Last spring, when I was at his laboratory in Würzburg, I examined with him blood that had been three weeks, a month, and five weeks, out of the body, preserved in little porcelain cups under glass shades. This blood was living and growing. Not only were the Amœba-like movements of the white corpuscles present, but there were abundant evidences of the growth and development of the corpuscles. I also saw a frog's heart still pulsating which had been removed from the body (I forget how many days,

but certainly more than a week). There were other examples of the same persistent vitality or absence of putrefaction. Von Recklingshausen did not attribute this to the absence of germs—germs were not mentioned by him; but when I asked him how he represented the thing to himself, he said the whole mystery of his operation consisted in keeping the blood *free from dirt*. The instruments employed were raised to a red heat just before use, the thread was silver thread and was similarly treated, and the porcelain cups, though not kept free from air, were kept free from currents. He said he often had failures, and these he attributed to particles of dust having escaped his precautions."

Professor Lister, who has founded upon the removal or destruction of this "dirt" great and numerous improvements in surgery, tells us the effect of its introduction into the blood of wounds. He informs us what would happen with the extracted blood should the dust get at it. The blood would putrefy and become fetid; and when you examine more closely what putrefaction means, you find the putrefying substance swarming with organic life, the germs of which have been derived from the air.

Another note which I received a day or two ago has a bearing particular significant at the present time upon this question of dust and dirt, and the wisdom of avoiding them. The note is from Mr. Ellis, of Sloane Street, to whom I owe a debt of gratitude for advice given to me when sorely wounded in the Alps. "I do not know," writes Mr. Ellis, "whether you happened to see the letters of which I enclose you a reprint, when they appeared in the *Times*. But I want to tell you this in reference to my method of vaccination as here described; because it has, as I think, a relation to the subject of the intake of organic particles from without into the body. Vaccination in the common way is done by scraping off the epidermis, and thrusting into the punctures made by the lancet the vaccine virus. By the method I use (and have used for more than twenty years) the epidermis is lifted by the effusion of serum from below, a result of the irritant cantharidine applied to the skin. The little bleb thus formed is pricked, a drop of fluid let out, and then a fine vaccine point is put into this spot, and after a minute of delay it is withdrawn. The epidermis falls back on the skin, and quite excludes the air—and not the air only, but what the air contains.

"Now mark the result—out of hundreds of cases of re-vaccination which I have performed, I have never had a single case of blood-poisoning or of abscess. By the ordinary way the occurrence of secondary abscess is by no means uncommon, and that of pyæmia is occasionally observed. I attribute the comparative safety of my method entirely, first, to the exclusion of the air and what it contains; and, secondly, to the greater size of the apertures for the inlet of mischief made by the lancet."

I bring these facts forward that they may be sifted and challenged if they be not correct. If they are correct it is needless to dwell upon their importance, nor is it necessary to say that if Mr. Ellis had resigned himself wholly to the guidance of the germ theory he could not have acted more in accordance with the requirements of that theory than he has actually done. It is what the air contains that does the mischief in vaccination. Mr. Ellis's results fall in with the general theory of putrefaction propounded by Schwann, and developed in this country with such striking success by Professor Lister. They point, if true, to a cause distinct from bad lymph for the failures and occasional mischief incidental to vaccination; and if followed up they may be the means of leaving the irrational opposition to vaccination no ground to stand upon, by removing even the isolated cases of injury on which the opponents of the practice rely.

We are now assuredly in the midst of practical matters. With your permission I will recur once more to a question which has recently occupied a good deal of public attention. You know that as regards the lowest forms of

* A Lecture delivered at the Royal Institution of Great Britain, June 9, 1871.

life, the world is divided, and has for a long time been divided, into two parties, the one affirming that you have only to submit absolutely dead matter to certain physical conditions to evolve from it living things; the other, without wishing to set bounds to the power of matter, affirming that in our day no life has ever been found to arise independently of pre-existing life. Many of you are aware that I belong to the party which claims life as a derivative of life. The question has two factors:—the evidence, and the mind that judges of the evidence; and you will not forget that it may be purely a mental set or bias on my part that causes me throughout this discussion from beginning to end, to see on the one side dubious facts and defective logic, and on the other side firm reasoning and a knowledge of what rigid experimental inquiry demands. But judged of practically, what, again, has the question of Spontaneous Generation to do with us? Let us see. There are numerous diseases of men and animals that are demonstrably the products of parasitic life, and such diseases may take the most terrible epidemic forms, as in the case of the silkworms of France in our day. Now it is in the highest degree important to know whether the parasites in question are spontaneously developed, or are wafted from without to those afflicted with the disease. The means of prevention, if not of cure, would be widely different in the two cases.

But this is by no means all. Besides these universally admitted cases, there is the broad theory now broached and daily growing in strength and clearness—daily, indeed, gaining more and more of assent from the most successful workers and profound thinkers of the medical profession itself—the theory, namely, that contagious disease generally is of this parasitic character. If I had heard or read anything since to cause me to regret having introduced this theory to your notice more than a year ago, I should here frankly express that regret. I would renounce in your presence whatever leaning towards the germ theory my words might then have betrayed. Let me state in two sentences the grounds on which the supporters of the theory rely. From their respective viruses you may plant typhoid fever, scarlatina, or small-pox. What is the crop that arises from this husbandry? As surely as a thistle rises from a thistle-seed, as surely as the fig comes from the fig, the grape from the grape, the thorn from the thorn, so surely does the typhoid virus increase and multiply into typhoid fever, the scarlatina virus into scarlatina, the small-pox virus into small-pox. What is the conclusion that suggests itself here? It is this:—That the thing which we vaguely call a virus is to all intents and purposes a *seed*; that, excluding the notion of vitality, in the whole range of chemical science, you cannot point to an action which illustrates this perfect parallelism with the phenomena of life—this demonstrated power of self-multiplication and reproduction. The germ theory alone accounts for the phenomena.

And here you see the bearing of the doctrine of Spontaneous Generation upon this question. For if the doctrine continues to be discredited as it has hitherto been, it will follow that the epidemics which spread havoc amongst us from time to time are not spontaneously generated, but that they arise from an ancestral stock whose habitat is the human body itself. It is not on bad air or foul drains that the attention of the physician will primarily be fixed, but upon disease germs which no bad air or foul drains can create, but which may be pushed by foul air into virulent energy of reproduction. You may think I am treading on dangerous ground, that I am putting forth views that may interfere with salutary practice. No such thing. If you wish to learn the impotence of medical science and practice in dealing with contagious diseases, you have only to refer to a recent Harveian oration by Dr. Gull. Such diseases defy the physician. They must burn themselves out. And indeed this, though I do not specially insist upon it, would favour the idea of their vital origin. For if the seeds of contagious disease be themselves living things,

it will be difficult to destroy either them or their progeny without involving their living habitat in the same destruction.

And I would also ask you to be cautious in accepting the statement which has been so often made, and which is sure to be repeated, that I am quitting my own *métier* when I speak of these things. I am not dealing with professional questions. I am writing no prescription, nor should I venture to draw any conclusion from the condition of your pulse and tongue. I am dealing with a question on which minds accustomed to weigh the value of experimental evidence are alone competent to decide, and regarding which, in its present condition, minds so trained are as capable of forming an opinion as on the phenomena of magnetism and radiant heat. I cannot better conclude this portion of my story than by reading to you an extract from a letter addressed to me some time ago by Dr. William Budd, of Clifton, to whose insight and energy the town of Bristol owes so much in the way of sanitary improvement.

"As to the germ theory itself," writes Dr. Budd, "that is a matter on which I have long since made up my mind. From the day when I first began to think of these subjects, I have never had a doubt that the specific cause of contagious fevers must be living organisms.

"It is impossible, in fact, to make any statement bearing upon the essence or distinctive characters of these fevers, without using terms which are of all others the *most distinctive of life*. Take up the writings of the most violent opponent of the germ theory, and, ten to one, you will find them full of such terms as 'propagation,' 'self-propagation,' 'reproduction,' 'self-multiplication,' and so on. Try as he may—if he has anything to say of those diseases which is characteristic of them—he cannot evade the use of these terms, or the exact equivalents to them. While perfectly applicable to living things, these terms express qualities which are not only inapplicable to common chemical agents, but, as far as I can see, actually inconceivable of them."

Once, then, established within the body, this evil form of life, if you will allow me to call it so, must run its course. Medicine as yet is powerless to arrest its progress, and the great point to be aimed at is to prevent its access to the body. It was with this thought in my mind that I ventured to recommend, more than a year ago, the use of cotton-wool respirators in infectious places. I would here repeat my belief in their efficacy if properly constructed. But I do not wish to prejudice the use of these respirators in the minds of its opponents by connecting them indissolubly with the germ theory. There are too many trades in England where life is shortened and rendered miserable by the introduction of matters into the lungs which might be kept out of them. Dr. Greenhow has shown the stony grit deposited in the lungs of stone-cutters. The black lungs of colliers is another case in point. In fact, a hundred obvious cases might be cited, and others that are not obvious might be added to them. We should not, for example, think that printing implied labours where the use of cotton-wool respirators might come into play; but I am told that the dust arising from the sorting of the type is very destructive of health. I went some time ago into a manufactory in one of our large towns, where iron vessels are enamelled by coating them with a mineral powder, and subjecting them to a heat sufficient to fuse the powder. The organisation of the establishment was excellent, and one thing only was needed to make it faultless. In a large room a number of women were engaged covering the vessels. The air was laden with the fine dust, and their faces appeared as white and bloodless as the powder with which they worked. By the use of cotton-wool respirators these women might be caused to breathe air more free from suspended matters than that of the open street. Over a year ago, I was written to by a Lancashire seedsman, who stated that during the seed season of each year his men suffered horribly from irritation and fever, so that many of

then left his service. He asked me could I help him, and I gave him my advice. At the conclusion of the season this year he wrote to me that he had simply folded a little cotton-wool in muslin, and tied it in front of the mouth; that he had passed through the season in comfort and without a single complaint from one of his men.

The substance has also been turned to other uses. An invalid tells me that at night he places a little of the wool before his mouth, slightly moistening it to make it adhere; that he has thereby prolonged his sleep, abated the irritation of his throat, and greatly mitigated a hacking cough from which he had long suffered. In fact, there is no doubt that this substance is capable of manifold useful applications. An objection was urged against the use of it: that it became wet and heated by the breath. While I was casting about for a remedy for this, a friend forwarded to me from Newcastle a form of respirator invented by Mr. Carrick, an hotel-keeper at Glasgow, which meets the case effectually, and by a slight modification may be caused to meet it perfectly.

We have thus been led by our first unpractical experiments into a thicket of practical considerations. Intaking the next step, a personal peculiarity had some influence upon me. The only kind of fighting in which I take the least delight is the conflict of man with nature. I like to see a man conquer a peak or quench a conflagration. I remember clearly the interest I took twenty years ago in seeing the firemen of Berlin contending for mastery with a fire which had burst somewhere near the Brandenburger Thor; and I have often experienced the same interest in the streets of London. Admiring as I do the energy and bravery of our firemen, and having heard that smoke was a greater enemy to them than flame itself, the desire arose of devising a fireman's respirator. But before I describe what has been done in this direction, let me draw your attention to the means hitherto employed to enable a man to live in dense smoke. Thanks to the courtesy of Capt. Shaw, I am enabled to show you the action of the "smoke-jacket," known abroad as the "Appareil Paulin," from its supposed inventor. The jacket is of pliable cowhide. It has arms and a hood, with eye-glasses. With straps and buckles the jacket is tied round the wrists and waist, and a strap which passes between the legs prevents it from rising. On the left side of the jacket is fixed a screw, to which the ordinary hose of the fire-engine is attached, and through the hose air instead of water is urged into the space between the fireman's body and the jacket. It becomes partially inflated, but no pressure of any amount is attainable, because the air, though somewhat retarded, escapes with tolerable freedom from the wrists and waist. Hence the fireman, when his hose is long enough, can deliberately walk in the densest smoke or foulest air. But you see the use of the smoke-jacket necessitates the presence of several men; it also implies the presence of an engine. A single man could make no use of it, nor indeed, any number of men without a pumping engine. Its uses are thus summed up in a communication addressed to me by Captain Shaw:—

"This smoke-jacket is very useful for extinguishing fires in vaults, stopping conflagrations in the holds of ships, and penetrating wells, quarries, mines, cesspools, &c.—any places, in short, where the air has become unfit for respiration.

"The special advantages of this jacket are its great simplicity, its facility for use, and the rapidity with which it can be carried about and put on; but its drawback is that it requires the use of an engine or air-pump, and consequently is of no service to one man alone. For this latter reason smoke-jackets, although very effective for enabling us to get into convenient places for extinguishing fires, have very rarely proved of any avail for saving life."

Now, it is that very want that I thought ought to be supplied by a suitable respirator. Our fire-escapes are each in charge of a single man, and I wished to be able to place it in the power of each of those men to penetrate

through the densest smoke into the recesses of a house, and there to rescue those who would otherwise be suffocated or burnt. I thought that cotton-wool, which so effectually arrested dust, might also be influential in arresting smoke. It was tried; but, though found soothing in certain gentle kinds of smoke, it was no match for the pungent fumes of a resinous fire, which we employ in our experiments in the laboratory, and which, I am gratified to learn from Captain Shaw, evolves the most abominable smoke with which he is acquainted. I cast about for an improvement, and in conversing on the subject with my friend Dr. Debus, he suggested the use of glycerine to moisten the wool, and render it more adhesive. In fact, this very substance had been employed by the most distinguished advocate of the doctrine of spontaneous generation, M. Pouchet, for the purpose of catching the atmospheric germs. He spread a film of glycerine on a plate of glass, urged air against the film, and examined the dust which stuck to it. The moistening of the cotton-wool with this substance was a decided improvement; still the respirator only enabled us to remain in dense smoke for three or four minutes, after which the irritation became unendurable. Reflection suggested that in combustion so imperfect as the production of dense smoke implies, there must be numerous hydrocarbons produced, which, being in a state of vapour, would be very imperfectly arrested by the cotton-wool. These in all probability were the cause of the residual irritation; and if these could be removed, a practically perfect respirator might possibly be obtained.

I state the reasoning exactly as it occurred to my mind. Its result will be anticipated by many present. All bodies possess the power of condensing in a greater or less degree gases and vapours upon their surfaces, and when the condensing body is very porous, or in a fine state of division, the force of condensation may produce very remarkable effects. Thus, a clean piece of platinum-foil placed in a mixture of oxygen and hydrogen so squeezes the gases together as to cause them to combine; and if the experiment be made with care, the heat of combination may raise the platinum to bright redness, so as to cause the remainder of the mixture to explode. The promptness of this action is greatly augmented by reducing the platinum to a state of fine division. A pellet of "spongy platinum," for instance, plunged into a mixture of oxygen and hydrogen, causes the gases to explode instantly. In virtue of its extreme porosity, a similar power is possessed by charcoal. It is not strong enough to cause the oxygen and hydrogen to combine like the spongy platinum, but it so squeezes the more condensable vapours, and also acts with such condensing power upon the oxygen of the air, as to bring both within the combining distance, thus enabling the oxygen to attack and destroy the vapours in the pores of the charcoal. In this way effluvia of all kinds may be virtually burnt up; and this is the principle of the excellent charcoal respirators invented by Dr. Stenhouse. Armed with one of these, you may go into the foulest-smelling places without having your nose offended. Some of you will remember Dr. Stenhouse lecturing in this room with a suspicious-looking vessel in front of the table. That vessel contained a decomposing cat. It was covered with a layer of charcoal, and nobody knew until told of it what the vessel contained.

I may be permitted in passing to give my testimony as to the efficacy of these charcoal respirators in providing warm air for the lungs. Not only is the sensible heat of the breath in part absorbed by the charcoal, but the considerable amount of latent heat which accompanies the aqueous vapour from the lungs is rendered free by the condensation of the vapour in the pores of the charcoal. Each particle of charcoal is thus converted into an incipient ember, and warms the air as it passes inwards. This is in entire accordance with the thermometric observations of Dr. Marcet.

But while powerful to arrest vapours, the charcoal res-

pirator is ineffectual as regards smoke. The particles get freely through the respirator. In a series of them tested downstairs, from half a minute to a minute was the limit of endurance. This might be exceeded by Faraday's method of emptying the lungs completely, and then filling them before going into a smoky atmosphere. In fact, each solid smoke particle is itself a bit of charcoal, and carries on it, and in it, its little load of irritating vapour. It is this, far more than the particles of carbon themselves, that produces the irritation. Hence two causes of offence are to be removed: the carbon particles which convey the irritant by adhesion and condensation, and the free vapour which accompanies the particles. The moistened cotton-wool I knew would arrest the first, fragments of charcoal I hoped would stop the second. In the first fireman's respirator, Mr. Carrick's arrangement of two valves, the one for inhalation, the other for exhalation, are preserved. But the portion of it which holds the filtering and absorbent substances is prolonged to a depth of four or five inches. On the partition of wire gauze at the bottom of the space which fronts the mouth is placed a layer of cotton-wool, moistened with glycerine; then a thin layer of dry wool; then a layer of charcoal fragments; a second thin layer of dry cotton-wool, succeeded by a layer of fragments of caustic lime. The succession of the layers may be changed without prejudice to the action. A wire-gauze cover keeps the substances from falling out of the respirator. In the densest smoke that we have hitherto employed, the layer of lime has not been found necessary; in a flaming building, indeed, the mixture of air with the smoke never permits the carbonic acid to become so dense as to be irrespirable; but in a place where the gas is present in undue quantity, the fragments of lime would materially mitigate its action.

In a small cellar-like chamber downstairs, with a stone flooring and stone walls, the first experiments were made. We placed there furnaces containing resinous pine-wood, lighted the wood, and placing over it a lid which prevented too brisk a circulation of the air, generated dense volumes of smoke. With our eyes protected by suitable glasses, my assistant and I have remained in this room for half-an-hour and more, when the smoke was so dense and pungent that a single inhalation through the undefended mouth would be perfectly unendurable: and we might have prolonged our stay for hours. Having thus far perfected the instrument, I wrote to Captain Shaw, the chief officer of the Metropolitan Fire Brigade, asking him whether such a respirator would be of use to him. His reply was prompt; it would be most valuable. He had, however, made himself acquainted with every contrivance of the kind in this and other countries, and had found none of them of any practical use. He offered to come and test it here, or to place a room at my disposal in the City. At my request he came here, accompanied by three of his men. Our small room was filled with smoke to their entire satisfaction. The three men went successively into it, and remained there as long as Captain Shaw wished them. On coming out they said that they had not suffered the slightest inconvenience; that they could have remained all day in the smoke. Captain Shaw then tested the instrument with the same result. From that hour the greatest interest has been taken in the perfecting of the instrument by Captain Shaw himself. He has attached to the respirator suitable hoods. The real problem is practically solved, and I can only say that if a tithe of the zeal, intelligence, and practical skill were bestowed on the cotton-wool respirator that Captain Shaw has devoted to the fireman's respirator the sufferings of many a precious life might be spared and its length augmented.*

The discourse was concluded as follows:—"Thus have we been led from the actinic decomposition of vapours

through the tails of comets and the blue of the sky to the dust of London, from the germ theory of disease down to this fireman's respirator. Instead of this trivial example, I could, if time permitted, point to others of a more considerable kind in illustration of the tendency of pure science to lead to practical applications. Indeed, those very wanderings of the scientific intellect which at first sight appear utterly unpractical, become in the end the well-springs of practice. Yet I believe there is a philosophy embraced by some of our more ardent thinkers (who I fear on many points commit the well-intentioned, but fatal mistake of putting their own hopeful fancies in the place of fact) that would abolish these wanderings of the intellect and fix it from the outset on practical ends alone. I do not think that that philosophy will ever make itself good in the world, or that any freedom-loving student of nature could or would tolerate its chains."

A short time before the discourse I had an opportunity of inspecting the apparatus of Mr. Sinclair, which has been tested and highly spoken of by the Superintendent of the Manchester Fire Brigade. The original idea is due to Von Humboldt, who proposed it for the Hartz mines. Galibert constructed the apparatus in an improved form, and it has been still further improved by Mr. Sinclair, who has purchased Galibert's patent. It consists of an air-tight bag, from which issue two tubes that unite on a single one with a respirator mouth-piece. The bag is filled with air, and the wearer inspires through one valve and expires through another. The expired breath is carried to the bottom of the bag, and is stated to remain there in consequence of the chilling experienced in its passage downwards. A bag of not inordinate size is said to be sufficient to supply a man with air for twenty minutes. Mr. Sinclair's apparatus was exhibited during the discourse.

ON THE SPECIFIC GRAVITIES INDICATED BY BAUME'S HYDROMETERS.*

By Dr. WILSON H. PILE, Philadelphia.

IN endeavouring to frame a simple rule or formula by which the degrees of Baumé's hydrometer could be reduced to their corresponding specific gravities, I was led to select the following illustration in determining the relation existing between the two scales, as being thus more readily comprehended than in any other way. Having never met with similar observations by others, I have endeavoured in the following paper to explain, as briefly as possible, the method by which the rules alluded to have been formed.

Without further preamble, and without going into any detail respecting the nature and principles of the hydrometer, which would be foreign to the subject, let a cylindrical tube of thin glass, closed at its lower extremity, be floated in water of the temperature of 60° F., dropping shot or mercury into the tube until it sinks within a short distance of the top; make a line at this point, which call the water-point; now divide the cylinder between this point and the bottom into 145 parts, and number these divisions from the water-line downwards; you will have thus formed a true Baumé's hydrometer for all liquids heavier than water, and, although very unlike the ordinary instrument, yet its indications will be perfectly reliable, provided the tube be of equal diameter throughout.

A question may here arise, why divide the scale into 145 parts? This division was selected as giving a scale corresponding with the average of a number of Baumé's

* Mr. Ladd has also proposed a form of mouth-piece which promises well, and Mr. Cottrell has attached to it an ordinary fencing-mask. This will probably be the form of apparatus finally adopted.

* From the *Proceedings of the American Pharmaceutical Association*, 1870.

hydrometers from different makers. Baumé himself left no practical or specific directions for this purpose. In fact, an examination of these instruments will, unfortunately, exhibit very wide discrepancies, thus rendering the indications unreliable.

RULE.

RULE.

$$\frac{145}{145 - B.} = \text{sp. gr.}$$

$$\frac{140}{B. + 130} = \text{sp. gr.}$$

$$145 - \frac{145}{\text{sp. gr.}} = B.$$

$$\frac{140}{\text{sp. gr.}} - 130 = B.$$

To remedy this as far as possible, Mr. Henry Pemberton, of Philadelphia, in 1851, proposed the scale as above described. This was adopted as the standard by the Philadelphia College of Pharmacy the same year, and thus was secured a uniform scale for this instrument.

You will bear in mind that the scale we have just been considering is for liquids that are heavier than water. Now, for liquids lighter than water, it would appear but natural that similar divisions should be continued upwards above the water-line. But it happens, unfortunately, that, from erroneous views taken by Baumé, which need not here be discussed, the degrees for light liquids are larger than those for heavy liquids, and it was found by Mr. Pemberton that an average of several hydrometers showed each degree to be about the $\frac{1}{10}$ th part of the scale instead of the $\frac{1}{15}$ th. To recur to our cylinder, the space below the water-line must be divided into 140 parts, and then similar divisions carried upwards as far as necessary.

All that part of the scale above the water-line will then indicate the degrees of Baumé for liquids lighter than water.

Another unfortunate idea of Baumé, and one which often leads to error, may here be alluded to. I refer to the numbering of the degrees for light liquids, calling the water-point in this scale 10° instead of 0°, and from thence increasing upwards.

I will remark here, that in the French Codex, published

in 1850, a modified Baumé's scale was ordered to be used, selecting one which would be equivalent to dividing our cylinder into 144 degrees, and retaining the same divisions for liquids lighter than water, but yet continuing the original idea of calling the water-point 10° for liquids lighter than water. Although the instrument, as thus modified, is undoubtedly an improvement over Baumé's scale, yet it does not appear to have been introduced into this country. The scale of this French hydrometer will be found in the appendix to Wood and Bache's "Dispensatory," together with that adopted by the College of Pharmacy of Philadelphia. To proceed with our subject, you will please remember the law of hydrostatics, "that a floating body always displaces a quantity of the liquid in which it floats, equalling in weight the total weight of the floating body itself." If, therefore, our cylinder, while immersed in water, displaces 145 parts, the number of parts which it displaces in any other liquid will necessarily equal the same weight; or, in other words, that number of parts of the liquid will weigh precisely as much as 145 parts of water. The density or specific gravity of the liquid will, of course, be in an inverse ratio to the number of parts displaced, and this relation holds good in whatever number of parts the cylinder is divided, and we have merely to divide the number of parts beneath the surface of the liquid into the number of parts to which it sinks in water to obtain the specific gravity of the liquid.

The diagram which I have here drawn will make this evident. No. I. represents the cylinder, divided into 145 parts for liquids heavier than water; in the adjoining column we see these divisions as numbered in Baumé's hydrometer; the third column gives the ratio which these degrees bear to water; and in the fourth column these fractions are reduced, showing the specific gravity. In the diagram No. II., the cylinder up to the water-line is divided into 140 parts, and then continued upwards as high as required; opposite is the corresponding Baumé's degrees, water being 10, next the ratio, and then the specific gravity.

We are thus enabled to see the relation existing between Baumé's degrees and their specific gravity, and also the rule by which one scale is reduced to the other.

For example, let it be desired to know the specific gravity of the tenth degree of Baumé for heavy liquids; we see by the diagram that this degree is 135 parts from the bottom, and, as has been shown, these 135 parts must equal in weight 145 parts of water, and therefore its specific gravity must be $\frac{145}{135}$ as great, or 1.074. Hence, the directions, subtract the given degree of Baumé from 145, and divide the remainder into 145, the quotient will be the corresponding specific gravity; expressed algebraically, the formula is—

$$\frac{145}{145 - B.^{\circ}} = \text{sp. gr.}$$

This is for liquids heavier than water; for lighter liquids, a variation of this formula is necessary, on account of the water-point being called 10. The principle is, however, identical in both cases; thus, to ascertain the sp. gr. of 50° Baumé, observe that this degree is but 40° above the water-line, and this, added to the 140 parts below that line, makes 180 parts in all below the fiftieth degree, and this sum divided into 140 will give the required specific gravity, or 0.7777.

The formula for this is—

$$\frac{140}{B.^{\circ} - 10 + 140},$$

or, which is the same—

$$\frac{140}{B.^{\circ} + 130} = \text{sp. gr.}$$

The converse of these rules, or to ascertain the degree of Baumé corresponding to any given specific gravity, is

found by a simple algebraic transfer of terms, and is as follows:—For heavy liquids—

$$145 - \frac{145}{\text{sp. gr.}} = B.,$$

and for light liquids—

$$\frac{140}{\text{sp. gr.}} - 130 = B.$$

A LECTURE EXPERIMENT.*

IN the phenomenon of the spheroidal state, the globule will float when the vapour beneath it is able to support the pressure of the atmosphere plus the weight of the globule. If we remove the former factor, a much smaller vapour tension will be required to produce the phenomenon, as may be proved by the following experiment, described by E. Budde,† in which, with the aid of the air-pump, a Leidenfrost globule is supported upon a metal plate whose temperature is below 100° C. A bell-shaped glass vessel, *g*, is firmly cemented to a copper plate, *a*. Through the

stopper which closed the upper opening pass two glass tubes, *l* and *m*. The first attaches by caoutchouc tubing to the air-pump. The second reaches within the vessel nearly to the plate *a*, while above it is closed and bent into an N form. The bent portion is filled with water. The plate is now placed upon the water-bath, which soon imparts to it a temperature of from 80° to 100° C. The air-pump is now put in operation; the water in *n* evolves air-bubbles and vapours (gentle heating will facilitate the operation) which mainly accumulate in the upper end of the tube—and force a portion of the water through *m*. The water falls boiling, or very nearly so, upon the plate beneath, the temperature of which is, under the abnormal conditions, considerably above the boiling-point of the water—and all the conditions necessary for the production of the spheroidal state are present. If the rarefaction is carried until the barometer indicates 10 c.m. (about 4 inches) of mercury, and the water-bath is heated to about 90° C., the experiment will succeed without the slightest difficulty, and the spheroids obtained will evince an energetic movement.

The experiment is not a mere physical curiosity, but possesses an importance which our educated readers will doubtless have already appreciated, inasmuch as it is

* From advance-sheets of the *Journal of the Franklin Institute*. Communicated by the Editors.
† *Pogg. Ann.*, vol. ccxviii., p. 158.

decisive in confirming the theory of the spheroidal state. It proves that the force which sustains the globule obeys the laws which govern the tension of vapours.

ON THE ESTIMATION OF PHOSPHORIC ACID.

By CHARLES E. MUNROE.

(Continued from p. 19).

Disodic Phosphate.—It is quite difficult to obtain this salt anhydrous. It becomes so between 30° and 40°, but as it fuses at 35°, it must be re-pulverised for analysis, and as it is quite hygroscopic, it is liable to change during the operation. A quantity dried over sulphuric acid was used, the phosphoric oxide being determined by ignition.

Grms.	Grms.	
(1). 1.1130	gave 0.4576	Na ₂ P ₂ O ₇ = 21.98 per cent P ₂ O ₅
(2). 1.2355	" 0.5075	" = 21.97 " "

The mercurous oxide process with cupric oxide gave the following results:—

	Found.	Theory.
(1). 1.0245 grms. gave 0.5124 grms. P ₂ O ₅	= 50.01	50.00
(2). 1.2198 " " 0.4716 " "	= 38.66	21.97
(3). 0.9200 " " 0.2018 " "	= 21.93	"
(4). 1.2423 " " 0.2730 " "	= 21.97	"

No. 1 was a specimen of anhydrous phosphate. It will be noticed that the second analysis is much too high. In this one the nitro-mercurous phosphate was placed in a mass in the centre of the crucible and completely covered with cupric oxide. When the crucible was heated the cupric phosphate formed coated the outside of the pellet and prevented the further escape of the mercury. This proves the necessity of mixing thoroughly.

Care should be taken that the mercurous nitrate used is not basic. The salt used in this investigation was prepared in the following way. Pure mercury was dissolved, by aid of gentle heat in pure nitric acid in a flat, open vessel. More mercury was now added and the whole boiled until every trace of nitrous acid was driven off. The solution was then allowed to crystallise. To the solution formed from these crystals metallic mercury is added to prevent the formation of mercuric nitrate. By this method the salt is obtained perfectly free from mercuric nitrate and the nitrites.

Ammonio-Sodic Phosphate.—As the ammonia present decomposes the mercurous nitrate, it is well to boil with a little caustic soda until it is driven off. In the first analysis magnesian oxide was substituted for the cupric oxide, but in every other respect the process was the same.

	Found.	Required.
(1). 1.3500 grms. gave 0.3991 grms. P ₂ O ₅	= 29.56	29.36
(2). 0.9832 " " 0.2902 " "	= 29.51	"
(3). 1.0803 " " 0.3181 " "	= 29.44	"

Mean 29.50

Ammonio-Magnesian Phosphate.—The solution was freed from ammonia as in the previous case. By ignition the following results were obtained.

Grms.	Grms.	
(1). 0.5936	gave 0.3664	Mg ₂ P ₂ O ₇ = 43.00 per cent P ₂ O ₅
(2). 0.6135	" 0.4123	" = 42.99 " "

By the mercurous nitrate process I obtained the following results:—

(1). 1.0785 grms. gave 0.4627 grms. = 42.92 per cent P ₂ O ₅	
(2). 0.9500 " " 0.4084 " = 42.98 " "	

Mean 42.95

Calcic Phosphate.—This salt was obtained by precipitating calcic chloride with an excess of disodic phosphate. The precipitate was then carefully washed and dried. This was dissolved in as little nitric acid as possible. If

the solution is too acid the precipitate is not formed until sodic hydrate is added. The nitro-mercurous phosphate was ignited with magnesian oxide. By this means the following results were obtained:—

(1). 0.6190 grms. gave 0.1606 grms. P ₂ O ₅ = 25.94 per cent	
(2). 0.6765 " " 0.1755 " = 25.96 " "	
Mean 25.95	

Mr. Waldo Lincoln employed this process in making an analysis of bone earth, and permits me to cite his results. The nitro-mercurous phosphate was ignited with cupric oxide.

	I.	II.	III.	IV.
Weight taken ..	0.5586	0.4312	0.7025	0.6969
" SiO ₂ found ..	0.0009	0.0007	—	—
" P ₂ O ₅ ..	0.2367	0.1487	0.2421	0.2396
Per cent SiO ₂ ..	0.1600	0.1600	—	—
" P ₂ O ₅ ..	42.3700	34.4800	34.4600	34.3800

Mean of P₂O₅ in three analyses, 34.44

The first analysis presents another instance of failure on account of the precipitate not being properly mixed with the cupric oxide.

Aluminic Phosphate.—This was prepared by adding an excess of disodic phosphate to a solution of potash alum. The precipitate thus obtained was carefully washed and dried. The phosphate was dissolved in the least possible quantity of nitric acid and then treated as in the previous cases. An excess of nitric acid must be carefully avoided. The precipitate was ignited with cupric oxide.

(1). 0.5685 grms. gave 0.1634 grms. P ₂ O ₅ = 28.77 per cent	
(2). 0.5827 " " 0.1672 " = 28.69 " "	
(3). 0.6720 " " 0.1927 " = 28.68 " "	

Mean 28.71.

In order to test the process thoroughly it was thought best to determine the composition of this salt and then to compare the found with the calculated percentage. The water was estimated by simple ignition:

(1). 0.8689 grms. gave 0.2624 grms. H ₂ O = 30.18 per cent	
(2). 0.8370 " " 0.2525 " = 30.17 per cent	

The aluminic oxide was taken by difference, yielding 41.12 per cent. These results lead to the formula

showing it to be a basic aluminic phosphate.

	Calc. per cents.	Found per cents.
P ₂ O ₅	28.86	28.71
H ₂ O	29.27	30.17
Al ₂ O ₃	41.87	41.12

I attempted to determine ferric and uranic phosphates in the same way, but on the addition of the sodic hydrate the metallic oxides were precipitated, rendering this method worthless for them. The iron solution was then very largely diluted and precipitated without the addition of sodic hydrate, but all of the phosphoric acid could not be thrown down. Next the ferric was reduced to the ferrous salt by the addition of metallic iron, by passing a stream of sulphydric acid through the solution, and by the addition of sulphuric acid, but without better results. The phosphate was dissolved in potassic cyanide and the ammonio-magnesian solution added to precipitate the phosphoric acid. I hoped that potassic ferrocyanide would be formed which would remain in solution and allow the phosphoric acid to combine with the potassium. The experiment, however, proved unsuccessful, and with these results the further investigation of ferric phosphate was suspended.

Although the ignition with cupric oxide leaves nothing to be desired in point of accuracy, and is a much quicker method than any now in use, yet it was thought that some other agent might be employed which would hasten the process still more.

Stannic oxide was tried for this purpose. To a weighed quantity of pure tin* the nitro-mercurous phosphate was added, then sufficient nitric acid, sp. gr. 1.170, was poured upon the mass to oxidise the tin completely. The whole was evaporated to dryness on a radiator, ignited and weighed. The plan seemed very promising, but the results, from some unknown cause, were far from being satisfactory.

Another idea was to fuse the nitro-mercurous phosphate with some substance which had a low fusing-point, so that the mercury might be volatilised, the phosphoric oxide remaining. Accordingly it was fused with free sulphur, but some of the phosphoric oxide was always volatilised. Potassic dichromate and plumbic chromate were both subjected to trial, but as the results were very unsatisfactory, further investigation in this direction was abandoned.

These results prove conclusively the value of this process for the estimation of phosphoric acid in all cases except those of ferric† and uranic phosphates.—*American Journal of Science.*

CORRESPONDENCE.

THE AMMONIA PROCESS.

To the Editor of the Chemical News.

SIR,—Will you allow me to call attention to the letter of Mr. Dugald Campbell, which appeared in the *CHEMICAL NEWS* of last week; and especially to the details, as far as they are given, of the experiment brought forward as a sample of many others.

Mr. Campbell took albumen, equivalent to 0.0014 grain or 0.0000909 grm. (9-100ths of a milligram.) of dry albumen, and distilled from a litre of water. Now, as a matter

of practical experiment, Messrs. Wanklyn, &c., state ("Water Analysis," p. 69) that 100 parts of dry albumen yield 10 parts of ammonia on distillation with potassic hydrate and potassic permanganate; consequently, from 9-100ths of a milligram of dry albumen Mr. Campbell might expect to obtain 9-100ths of a milligram of ammonia. This struck me as an excessively small quantity, and, on hunting up the delicacy of the Nessler test, I find that Messrs. Wanklyn, &c. (who may fairly be supposed not to underestimate its delicacy), state ("Water Analysis," p. 45) that 1-200th of a milligram of ammonia in 100 c.c. of water, or 1-100th in 200 c.c., is the limit of accuracy to be relied on for quantitative work.

To distil off the whole of the ammonia from the albumen taken in the above experiment at least 200 c.c., or, better, 300 c.c., must be driven over. The least quantity of ammonia estimable in this distillate would be therefore 1-100th of a milligram, so that Mr. Campbell took a trace of albumen which would yield him a quantity of ammonia—9-100ths of a milligram,—rather less than the least quantity—1-100th of a milligram,—that can be fairly estimated by the Nessler test in 200 c.c. of water, and accordingly found in his distillate only a trace of colour on the addition of the Nessler reagent.

It seems to me that the above experiment of Mr. Campbell proves, in a most striking manner, the accuracy and delicacy of the method under discussion, since it has yielded, in Mr. Campbell's own hands, results slightly more delicate and accurate than those obtained by its authors.

Two rather important data are not given by Mr. Campbell. (1). He does not state whether the water he used was freed from ammonia, &c., before adding the albumen, and consequently leaves the question, as to whether ammonia was or was not obtained on boiling the albumen with sodic carbonate, unanswered. (2). He does not give the quantity distilled over after adding the potassic permanganate, &c.; at least 200 c.c. should have been distilled under the circumstances.—I am, &c.,

SCRUTATOR.

July 18, 1871.

THE AMMONIA PROCESS.

To the Editor of the Chemical News.

SIR,—Mr. Campbell's statement, that a dilute solution of albumen yields its nitrogen in the form of ammonia when it is boiled with carbonate of soda, is an error. In reference to the experiment which Mr. Campbell brings forward, it is sufficient to remark that the total ammonia obtainable by our process from the white of egg taken by him did not exceed the 1-100th of a milligram.—We are, &c.,

J. ALFRED WANKLYN.
ERNEST T. CHAPMAN.

London, July 17, 1871.

CORRELATION OF ELECTRICAL AND CHEMICAL FORCE.

To the Editor of the Chemical News.

SIR,—Will you allow me, through the medium of your journal, to call the attention of chemists to one or two facts which seem to have been elicited in some experiments which I have been recently trying.

1. In a compound galvanic circuit, I have found that considerably more zinc is consumed in an electrolyte of chloride of sodium than in one of nitrate of soda and other electrolytes. Believing, as a general rule, in the law of changes in the same circuit in exact proportion to the chemical equivalents, I attributed this to a greater local action in chloride of sodium than in nitrate of soda. But in placing zinc for some days in solutions of nitrate of soda and of chloride of sodium, I found no appreciable

* Chemically pure tin can be obtained in considerable quantities and with very little trouble, in the following manner. Ammonio-stannic chloride is first produced by adding to one molecule of stannic chloride, two of sal-ammoniac. Dissolve in the least possible quantity of water and add an excess of chlorhydric acid, which causes the double chloride to crystallise out immediately. Purify completely by re-crystallisation from acid solutions. Dry the salt at 120°. Then fuse with an equal weight of a mixture of one part of potassic cyanide and one of potassic carbonate in a porcelain crucible. On cooling, a button of chemically pure tin will be found.

† Rose proposes in the case of ferric phosphate, to fuse the mercurous phosphate obtained with the mixed carbonate; then dissolve in dilute chlorhydric acid, and precipitate with the ammonio-magnesian solution. This will not effect a complete separation.

Otto's process of precipitating the phosphoric acid as ammonio-magnesian phosphate in the presence of tartaric acid was modified and tested as follows:—Ferric phosphate was prepared by precipitating ferric chloride with disodic phosphate. The precipitate was thoroughly washed by decantation and then evaporated to dryness. By this means the phosphate was obtained as a light yellow powder. A weighed quantity of this was dissolved in dilute chlorhydric acid, sufficient tartaric acid added to keep the whole of the iron in solution, next ammonia in excess, the solution was then heated till it boiled briskly, and the ammonio-magnesian solution was added. The precipitate was ignited and weighed as magnesian pyrophosphate. This method gave the following results:—

(1).	0.6084 grms.	gave 0.3437 grms.	$Mg_2P_2O_7 = 36.13$	per cent P_2O_5
(2).	0.7411	" " 0.4173	" "	" = 36.02
(3).	1.0294	" " 0.5805	" "	" = 36.11
		Mean	36.09.	

I would call especial attention to the fact, as it shortens the process considerably, that the phosphate solution was boiling when the ammonio-magnesian solution was added. Dr. Gibbs found that when the ammonio-magnesian and ammonio-manganic phosphates were precipitated from boiling solutions, that on cooling they came down as beautiful, highly crystalline precipitates, which, instead of requiring twenty-four hours for precipitation, were ready to be filtered within an hour. This method has been in use in this laboratory for the past six months, and has met with uniform success. It applies as well to the estimation of phosphoric acid as to that of magnesium and manganese.

With this additional treatment for the separation of iron, it is believed that this process will apply to the majority of cases met with in practice.

waste in either. I am aware there have been many facts which have seemed to militate against the law of change according to definite chemical equivalents; and, in this case, the difference of zinc consumed was so great as to suggest the idea that as zinc and chlorine produce much less heat in their combination than zinc and oxygen, and, consequently, I presume, less electricity, it might be possible that such equivalents might be consumed as would produce an equal amount of heat. The facts were not inconsistent with this supposition. But there are so many sources of error in these experiments, that I only wish to draw the attention to the subject of such chemists as have an opportunity of experimenting with greater accuracy than myself.

2. Though zinc is soluble in alkalies, I was surprised to find that zinc and carbon, in an electrolyte of caustic soda, or its carbonates, produce scarcely any action whatever, and what little they do produce very soon ceases altogether. In acids, or ordinary neutral salts, of course the action is very powerful, till weakened by polarisation.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney,
July 15, 1871.

ESTIMATION OF PHOSPHORIC ACID.

To the Editor of the Chemical News.

SIR,—In Mr. Munroe's paper on the above subject (CHEMICAL NEWS, vol. xxiv., p. 18) the percentage of Al_2O_3 in "pure aluminic sulphate, $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$," obtained by that gentleman is 17.88 per cent; the percentage of P_2O_5 obtained in "ammonio-sodic phosphate, $\text{Na}(\text{NH}_4)\text{HPO}_4 \cdot 4\text{H}_2\text{O}$," is 29.36 per cent. As my calculations from these formulæ give very different results to the above, may I ask Mr. Munroe to explain the difference between his results and the theory.—I am, &c.,

B. J. GROSJEAN.

MISCELLANEOUS.

Quality of the Gas Supplied to the Metropolis.—Dr. Letheby, the Chief Gas Examiner appointed by the Board of Trade, has recently submitted to the Corporation of London and Metropolitan Board of Works his quarterly report of the gas supplied to London by the Chartered, the Imperial, and the South Metropolitan Gas Companies, from which it appears that the average illuminating power of the gas at the different testing stations has been as follows:—Chartered Gas, at Cannon Street, 17.70 sperm candles; at Gray's-Inn Road, 17.41 candles; at Friendly Place, Mile End, 17.56 candles; at Arundell Street, Haymarket, 17.49. Imperial Gas, at Oakley Square, 15.72; at Camden Street, 15.47; at Graham Street, 16.68. South Metropolitan, at Hill Street, Peckham, 15.88 candles. As regards the illuminating power of the Cannel gas it was equal to an average of 25.48 candles at Cannon Street, and 24.81 candles at Arundell Street. The gas of all the companies at all the testing places has been constantly free from excess of ammonia and from sulphuretted hydrogen, but the amount of sulphur in the gas has fluctuated to a large extent, as from an average of only 12.58 grains per 100 cubic feet of the Cannel gas of the Chartered Company at Cannon Street, to 40.73 grains per 100 feet of the common gas at Gray's-Inn Road. The average proportions of sulphur in the gas at the several testing places have been as follows:—Cannel gas of the Chartered Company, at Cannon Street, 12.58 grains per 100 cubic feet; at Arundell Street, 26.71 grains. Common gas of the Chartered Company, at Friendly Place, 22.47 grains; at Cannon Street, 28.32 grains; at Arundell Street, 30.66 grains; at Gray's-Inn Road, 40.73 grains. Imperial gas, at Camden Street, 25.02 grains; at Graham

Street, 27.90 grains; at Oakley Square, 34.28 grains. South Metropolitan gas, at Hill Street, Peckham, 29.26 grains. Dr. Letheby reports that the most notable feature in the quality of the Chartered gas supplied during the quarter has been the excessively large proportion of sulphur, as compared with that contained in the gas at several of the testing places in the corresponding quarter of last year; and, as this increase has been coincident with the opening of the new works at Beckton, he thinks that the processes of manufacture and purification are not as perfect in the new works as they might be.

The Phenomena of Vibration.—A simple apparatus for the observation of some beautiful phenomena can be constructed as follows:—A disk of white cardboard, with apertures oblong in radial direction, is set on a spindle, so as to be rotated at any requisite speed. To examine, for instance, the flame of a gas light (in a glass tube, to prevent disturbance by air currents), place the disk in front of the light, so that the eye can see the light through each slit as it comes to a vertical position. If the speed of the disk's rotation is such that the interval of time between two slits passing the eye is just equal to the period of a vibration of the flame, the flame appears to be motionless; but if the velocity be reduced, the flame is seen to go slowly through its changes of form. If the interval be equal to, or one-half of, or one-third of the period of the vibration of the light, the illusory appearance of a disk having as many, or twice, or three times the number of slits really in the disk is seen. This phantom disk will appear to be motionless when the periods coincide; but when otherwise, it revolves in one direction or the other. It is obvious that the vibrations of the flame can be easily counted by this means. The inventor, Mr. Charles J. Watson, counted, with a sixteen inch tube, 453 vibrations of the flame per second. By this instrument, the undulation of the vibrations of a wire can be seen to travel up and down the wire; and if watched by both eyes through the slits, the spiral course of the undulations can be observed.—*Scientific American*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 11 1871.

This number contains the following original papers and memoirs:—

Hydrated Carbonate of Lime.—C. Rammelsberg.—The author's attention having been accidentally called to some very small crystals adhering to a confera (a water plant) in a pond, he examined these crystals, and found them to consist of hydrated carbonate of lime, containing 5 molecules of water. This compound was first observed by Pelouze, in a solution of lime in sugar water. This hydrate is characterised by the property of losing its water of hydration at a temperature above 15°, even when it is kept under water.

Camphoric Acid.—F. Wreden.—The first portion of this paper is devoted to the record of the labours of other chemists on this subject, among them R. Brandes (who, as far back as 1823, described the compound of camphor with nitric acid), J. von Liebig, Kachler, and others. The author next describes his process for making camphoric acid, which essentially consists in treating camphor with nitric acid (1.27 sp. gr.) in a large glass flask fitted in the neck with a glass tube which reaches to the bottom of the flask, but is somewhat drawn out, while it is hermetically fastened in the neck by means of gypsum, the open end of the tube being bent, so as to communicate with a flue. The flask is heated for fifty hours in a water-bath; by this mode of preparation a larger quantity of camphoric acid is obtained, the nitric acid is more completely utilised, and the operator is not incommoded by the nitrous fumes.

Regularity of the Atomic Weights.—M. Zængerle.—The value of this excellent memoir depends chiefly on the contents of the tabulated form annexed to it, and far too lengthy to be here reproduced.

On Aurine.—R. S. Dale and C. Schorlemmer.—The substance first obtained in 1861 by Kolbe and Schmitt, by heating phenol along with oxalic and sulphuric acids, has, as is well known, become an article which is regularly prepared in this country on the large scale, and is sold under the name of aurine or yellow coralline. The authors, having investigated this substance, state that the article alluded to is a mixture of different substances. The colouring matter in a pure state is obtained by the action of strong acetic acid, either in the form of chrome-red brilliant diamond-like needles, or in the shape of very small acicular crystals exhibiting a deep red colour with a steel-blue hue; these contain water of crystallisation, which is driven off at 160°, the substance thereby assuming a deep greenish metallic hue. The formula of the anhydrous combination is $C_{24}H_{12}O_8$, that of the red crystals $C_{24}H_{12}O_8 + 2H_2O$, and that of the steel-blue crystals $C_{24}H_{12}O_8 + 2H_2O$. By reducing agents, a colourless compound is obtained, which crystallises from an acetic acid solution in prismatic, transparent, yellow-coloured crystals, not containing any water; the formula of this body is $C_{24}H_{12}O_4$. The authors are engaged with other experiments on this subject.

Two Modifications of Benzo-Phenon.—Th. Zincke.—The contents of this lengthy paper record the author's experiments, made with the view to ascertain whether a substance obtained by him from diphenyl-methan is, or is not, a benzo-phenon. The result is that there exist two modifications of this body, both fusing at 300°—one of them crystallising in rhombic-shaped crystals boiling at 49°, the other belonging to the monoklinic crystal system, and fusing at 26°.

Action of Sodium Amalgam upon Oxalic Ether.—A. Eghis.—This paper contains chiefly the detailed description of a series of experiments made by the author in order to verify his former researches on this subject, which had led him to the conclusion that, by the action of sodium amalgam, there is formed glycolic acid, whereas S. Friedländer states that this is an error, and should be glycolinic acid. The author of this paper has, therefore, made a series of comparative investigations, the result of which is decidedly that glycolic acid is the result of the reaction alluded to. The formula of the calcium salt of this acid is $C_2H_2CaO_4 + 2H_2O$; this salt forms, with chloride of calcium, a double salt, $C_2H_2CaO_4 + CaCl_2 + 3H_2O$, crystallising in octahedra.

Solubility of Sulphide of Carbon in Alcohol.—The text books on chemistry state that sulphide of carbon is soluble in (miscible with) alcohol in every proportion. This assertion is not, according to the authors, correct, since a point of saturation is reached which depends entirely upon the quantity of water contained in the alcohol. The authors describe in this paper a series of experiments on this subject, made also with the view of applying the degree of solubility of sulphide of carbon in alcohol to the determination of the strength of the latter fluid, it having been found that sulphide of carbon is only miscible in all proportions with perfectly anhydrous alcohol. The temperature, moreover, plays an important part in this matter, since below 15° the solubility of sulphide of carbon in alcohol is greatly decreased. From the extensive details quoted in this paper we give the following instances:—Temperature, 17°; quantity of alcohol employed, 10 c.c.; percentage, by weight, of alcohol, 98.5; dissolved 18.2 c.c. of sulphide of carbon; alcohol at 93.54 per cent dissolved 7.0 c.c. sulphide; alcohol at 84.12 dissolved 3.0 c.c.; alcohol at 48.40 dissolved 0.20 c.c.; alcohol at 47.9 dissolved 0.0 c.c. This paper further contains a series of algebraic formulae by the aid of which the strength of alcohol may be calculated from experiments made in regard to its behaviour with sulphide of carbon.

Evolution of Heat by Neutralisation of Acids with Bases.—J. Thomsen.

Incorrectness of the Thermo-Chemical Researches made by Favre and Silbermann with the Mercurial Calorimeter.—J. Thomsen.

Some Observations and Critical Remarks.—J. Thomsen.

Researches on the Ether Derivatives of the Polyatomic Alcohols and Acids.—(Seventh part.)—L. Henry.—This portion of the monograph treats on the monochlorides of the biatomic and bibasic acids, and is divided into the following sections:—Oxalic ether-chloride—

succinic ether chloride—

oxamin-acid-ethyl; phenyl-oxamin-acid-ethyl; action of urea upon chloro-carbonic ether.

Propylen Compounds.—L. Henry.—This paper, as also the preceding one, is so filled with lengthy and complex formulae, essentially required for the proper elucidation of the contents, that any useful abstraction is impossible.

Primary and Secondary Phosphine of the Methyl Series.—Dr. A. W. Hofmann.—In the lengthy introduction to this essay, the eminent author describes in detail the mode of preparation and purification of the phosphines of the methyl series. Methyl-phosphine—

is a colourless, transparent, very nasty smelling, non-permanent gas,

which, by strong pressure, as well as by cold, becomes a colourless fluid, lighter than water, and boiling at -14° . The gas is insoluble in water, and nearly so in ether, but readily soluble in alcohol; it has a very great affinity for oxygen, and ignites spontaneously at a gentle elevation of temperature. Methyl-phosphine forms, with acids, salts, which are all decomposed by water, and have the property of bleaching vegetable colours as chlorine does. Two of these salts, the chlorhydrate and iodhydrate, are described at length as regards their preparation and properties. Dimethyl-phosphine—

is a colourless fluid, lighter than, and insoluble in, water; it boils at 25° , and is an exceedingly oxidisable body which, in contact with air, bursts violently into flame. This base also combines with acids, forming very readily salts soluble in water. Dimethyl-phosphine also combines with sulphur and sulphide of carbon. The author states that he intends to continue the researches on this subject next winter.

Azo-Compounds of Resorcin.—P. Weselsky.—Although the author states that this lengthy paper is only to be considered as a preliminary notice, we can only quote the headings of the sections into which it is divided, for the reason that the paper would require, for its proper understanding, the reproduction of very lengthy and complex formulae. The author states that very many of the compounds he has discovered are dyes *par excellence*, and will, no doubt, at some future day, be prepared industrially on the large scale. The titles of the sections alluded to are—Diao-resorcin, $\text{C}_{12}\text{H}_{12}\text{N}_2\text{O}_6$; diazo-resorufin, $\text{C}_{12}\text{H}_{12}\text{N}_2\text{O}_6$; salts of this base; tetra-azo compounds; nitric acid tetra-azo-resorcin, $[\text{C}_{12}\text{H}_4\text{N}_4\text{O}_6 + 3\text{NO}_2]$; nitric acid tetra-azorufin, $[\text{C}_{12}\text{H}_4\text{N}_4\text{O}_6 + 6\text{NO}_2]$; salts of this base; mono-nitro-resorcin.

Annalen der Chemie und Pharmacie, June, 1871.

This number contains the following original papers and memoirs:—

On Acridine.—C. Græbe and H. Caro.—The substance just named is obtained from crude anthracen, by treating that material with dilute sulphuric acid, and precipitation of this solution with bichromate of potassa. The dirty brown-coloured precipitate which ensues is repeatedly treated with boiling-water. From the cooled liquid, orange-yellow coloured crystals of chromate of acridine are deposited. These crystals, having been well washed, are next treated with ammonia, and the base thus set free is washed with cold water, and thus freed from chromate of ammonia. When quite pure, acridine is a colourless crystalline body; fuses at 107° ; boils, without decomposition, at 360° ; is very difficultly soluble in boiling water, and not at all in cold; readily soluble in alcohol, ether, sulphide of carbon, and hydrocarbons; its dilute solutions exhibit, in reflected light, a beautifully blue colour. Solutions of acridine (this name is given by the authors to this substance, owing to its corrosive biting action upon the skin of the hands and mucous membranes) exhibit, when tested with red-coloured litmus paper, distinctly an alkaline reaction. The formula of acridine is $\text{C}_{13}\text{H}_9\text{N}$, but the authors state that ulterior researches will be required to prove the correctness (in a structural and constitutional sense) of this composition. The main portion of this exhaustive monograph is further devoted to the following subjects:—Description of the salts of acridine; iodethyl combinations of acridine; nitro-derivatives of acridine; hydro-acridine, $\text{C}_{13}\text{H}_{10}\text{N}_2$; insoluble hydro-acridine.

Eugenol and Methoxybenzoic Acid.—C. Græbe and E. Borgmann.—The contents of this paper mainly record the result of the authors' experiments on the action of a mixture of bichromate of potassa and glacial acetic acid upon eugenol-methyl-ether, the result being the formation of bimethoxybenzoic acid, just as happens with cresol-methyl-ether. The bimethoxybenzoic acid, $\text{C}_{10}\text{H}_8\text{O}_4$, is, in some respects, akin to anisic acid, is difficultly soluble in cold, but more readily so in boiling water, forms needle-shaped crystals, dissolves readily in alcohol and ether, and fuses at 180° . The formula of eugenol is—

the direct oxidation of this body to an acid did not succeed.

On Pyren.—C. Græbe.—This monograph contains the following sections:—Preparation of pyren. Composition of pyren; formula, $\text{C}_{16}\text{H}_{10}$. (The reader is also referred to *CHEMICAL NEWS*, vol. xxii., p. 102, where a brief abstract of a paper on this subject, by the same author, is given.) Pyren exhibits, in pure state, large rhombic-shaped crystals; fuses at 142° ; boils at 360° , without decomposition; is difficultly soluble in cold alcohol, but more readily so in that liquid when boiling; and easily soluble in benzol and sulphide of carbon. Pyren is characterised by its behaviour with picric acid, forming therewith a compound, $\text{C}_{16}\text{H}_{10} + \text{C}_6\text{H}_2(\text{NO}_3)_3\text{OH}$. Nitro-derivatives of pyren; brom-derivatives; pyren-chinon, $\text{C}_{16}\text{H}_8\text{O}_2$; pyren-hydride; pyren-hexahydride, $\text{C}_{16}\text{H}_{16}$; constitution of pyren.

On Chrysen.—C. Liebermann.—The author opens this lengthy memoir with a review of the labours of Laurent, Williams, Galletly, Vogel, and many other chemists on this subject, and next describes, at great length, the very laborious task of obtaining chrysen, in pure state, from coal-tar. When quite pure, chrysen is a colourless body, fusing at about 250° ; it boils at a temperature higher than the boiling-point of mercury; formula, $\text{C}_{18}\text{H}_{12}$. This memoir contains, further, the following sections:—Mono-nitro-chrysen; tetra-nitro-chrysen;

brom-chrysen; chryso-chinon; chryso-hydro-chinon; dichlor-chryso-chinon and decachlor-chrysen; tetra-nitro-chryso-chinon.

Behaviour of Arsenic Acid with Hydrochloric Acid.—J. Mayrhofer.—This paper contains the record of the results of some experiments made with the view to ascertain under what conditions and in what state of combination arsenic is carried over by the distillation of hydrochloric acid which is contaminated with arsenic. It appears that the degree of concentration of the last-named acid, and the relative proportion of arsenic acid present, and also the care taken in cautiously distilling, are of influence in obtaining an arsenic-free distillate; but, moreover, the treatment of the hydrochloric acid with some chlorine, or, better still, sulphuretted hydrogen, previous to distillation, to be next carefully conducted, will ensure the distillate being free from arsenic.

Decomposition of Chloride of Phosphorus by Water.—K. Kraut.—It appears that, when chloride of phosphorus is poured into ice-cold water, it may be mixed therewith, forming a clear, or, at least, barely turbid liquid, from which phosphorus only separates after some days; but, if the same experiment be made with boiling water, there ensues a violent action, attended with combustion and the separation of a large quantity of amorphous phosphorus. With tepid water, the action is less violent, but the effect similar, and the same again happens when an excess of the chloride is treated with a small quantity of water.

Fourteenth Treatise on the Determination of the Chemical Position of some of the Toluol Derivatives.—F. Beilstein and A. Kuhlberg.—This portion of this very exhaustive monograph contains the following chapters:—Derivatives obtained by starting from dinitro-toluol; derivatives of para-toluidine; derivatives of meta-toluidine; derivatives of ortho-toluidine; isomeric toluenyl-diamines.

Carnin, a new Base met with in Extract of Meat.—Dr. H. Weidel.—This treatise contains the record of the author's experiments made with large quantities of extract of meat with which Prof. von Liebig kindly supplied him, the chief result being the discovery of a new organic base, present to about 1 per cent in the extract. The mode of preparing carnin is a tedious and rather complicate process. Carnin is, in pure state, a crystalline solid, insoluble in cold, readily soluble in boiling water, and insoluble in alcohol and ether. Carnin has a bitter taste, a neutral reaction, and is not precipitated by neutral acetate of lead. Formula, $C_8H_8N_2O_3$; being different from the formula of theobromine, $(C_7H_7N_2O_2)$, by only one atom of oxygen. The author describes a series of salts of carnin, and devotes a large portion of his paper to the description of physiological experiments made with this newly-discovered organic base.

Annales de Chimie et de Physique, November, 1870.

This number contains the following original papers:—

Memoir on the Acetic Derivatives of the Carbohydrates.—viz., Mannite and some substances isomeric therewith—and of other Immediate Vegetable Principles. —Dr. Schützenberger. —The continuation and end of this lengthy essay.

Inequality of the Loss of Acid and of Salt in the Vicinity of the Poles of a Galvanic Battery.—E. Bourgeois.—The author first gives a review of the labours of Daniell, Miller, Pouillet, Hittorf, Grothuss, d'Almeida, and others on this subject, and next describes at length a series of experiments, from which the following main results may be deduced:—When the galvanic current passes through acidulated water, it will be seen that, though the total effective work done by each pole is the same, the quantity of acid found in each compartment at the end of the experiment will be found to vary considerably. The three following cases may be distinguished:—(1) The acid is accumulated regularly at the positive pole; this occurs with sulphuric, nitric, phosphoric, benzoic, succinic, camphoric, &c., acids. (2) There is no loss at the positive pole; the loss is only experienced at the negative pole, since half of the electrolysed acid is regenerated in the other compartment. (3) The two compartments become simultaneously poorer; this occurs with lactic, tartaric, citric, and, in general, all the very readily oxidisable acids.

Chemico-Crystallographical Investigations on the Ferrocyanides.—Dr. Wybrouff.—The continuation of an essay commenced in the third series (the present number belongs to the fourth series) of this periodical. This portion is illustrated with a series of engravings, and the contents belong strictly to crystallography.

December, 1870.

The following original memoirs and papers are published in this number:—

Action of the Haloids in Free State, and of some Chlorides, upon Glucose.—A. Colley.—The contents of this lengthy essay describe the action of dry chlorine, bromine, and iodine upon anhydrous glucose, $C_6H_{12}O_6$. The result of the experiments is, that dextro-grating glucose is a pentatomic compound—that is to say, that it contains five oxyhydriles, (OH), capable of being exchanged for acids, &c.; and, since glucose contains six atoms of oxygen, one of these must be combined in another manner than that of an oxyhydril; but in what manner is not clearly elucidated by the author, who gives on this point some speculative theories not proved by experiment.

Superficial Tension of Liquids.—E. Duclaux.—A lengthy algebraico-physical essay illustrated with woodcuts exhibiting geometrical figures.

Heat Evolved by the Combustion of Coal.—A. Scheurer-Kestner and C. Meunier.—This extensive monograph, illustrated with woodcuts, is a most valuable specimen of the application of high

scientific and practical knowledge, and exceeds any work hitherto done in this direction. This essay is, however, far too lengthy for either useful abstraction or for complete translation.

Journal für Gasbeleuchtung und Wasserversorgung, No. 11, 1871.

This number only contains matter strictly belonging to gas- and water-works' engineering and management.

Bulletin Mensuel de la Société Chimique de Paris, November, 1870.

From the *procès-verbaux* of the meetings of this Society published in this number, we abstract the following matter:—

Acetate of Alumina Useful for the Purpose of Rendering Woven Fabrics Waterproof without thereby Impeding the Passing Off of the Perspiration.—Prof. Balard.—The author prepares the acetate of alumina by dissolving 30 grms. of acetate of lead in $\frac{1}{2}$ a litre of water (best distilled), and also 24 grms. of sulphate of alumina in half a litre of water. These solutions, having been mixed, are next filtered, after which the fabric is immersed therein for a quarter of an hour, and, after having been well drained, is dried in the air.

Substances which yield Nitrate of Potassa.—MM. Thiercelin and Willm.—It should hereby be observed that, at a comparatively remote period, saltpetre was regularly manufactured in most European countries by a process too long to be further alluded to here, and well known, undoubtedly, to most of our readers. The authors state that the richness of the saltpetre-yielding materials recently tested by them varies very much. They found that the efflorescence now and then met with, especially on the walls of old stables, contained as much as 67 per cent of saltpetre; but this material is rare. Old wood-ash yielded $\frac{1}{2}$ per cent; the mortar of a wall covered with ivy yielded 2.6 per cent; and the mortar of the same wall at a spot not covered with that plant, 4.6 per cent of saltpetre.

This number contains, moreover, the following original papers and memoirs:—

Saltpetre Industry in France before the Nineteenth Century.—Dr. Berthelot.—This memoir, a valuable contribution to the history of industrial chemistry, is far too lengthy for any useful abstraction; it contains the following chapters:—History of the saltpetre manufacture in France from the oldest times up to the beginning of this present century; report on saltpetre by the Scientific Committee for the Defence of Paris; nature and richness of the materials capable of yielding saltpetre in Paris; processes to be applied for the collection of these substances; hints for utilising and properly collecting ash and other materials which may yield saltpetre.

Preliminary Notice relating to Etherification.—M. Lorin.—The polyatomic alcohols, properly so-called, decompose, under 100°, oxalic acid into water, carbonic and formic acids, yielding thereby formic of the alcohol employed, and aqueous formic acid, containing 56 per cent of formic acid, according to the following formula:— $C_4H_8O_8 + HO = C_2O_4 + C_2H_4O_4 + HO$.

Preliminary Notice on the Formation of the Amides of the Fatty Acids.—M. Lorin.—The decomposition of the tartrate of ammonia, either acid or neutral, yield, at 200°, among their products of decomposition, water, carbonate and acetate of ammonia, and formiamide. The details of these experiments will be published at a future date.

NOTES AND QUERIES.

Kelp Liquors.—(Reply to "Iodine Manufacturer.")—It is not easy to state precisely the cause of the action of kelp liquors upon the iron, since it would be necessary to know all the conditions of the case. It may be, and very probably is, caused by the decomposition of the chloride of magnesium, whereby some hydrochloric acid is set free, which, of course, will attack the iron and blacken the salts; but there may exist other causes, which depend upon conditions, which, without a special investigation, cannot be explained and remedied. It is in this instance, as in many others, "*cessante (sublata) causa, cessat effectus*."

Temperature of the Sea.—(Reply to "Thermo.")—This subject belongs to physical geography, and we need hardly call your attention to the fact that the temperature, especially at the surface, of the sea must, of necessity, vary, in consequence of a great many causes which influence it, as, for instance, the latitude, shallowness, surrounding coasts, and water discharged from rivers. It is, therefore, clear that no concise answer can be given to your query; but, by consulting either Berghaus's "Physikalischer Atlas," or other works on physical geography, or the article "Sea" in any encyclopedia, say Chambers's, vol. viii., p. 581, you will there find full information on this subject. The works herein alluded to may be inspected at the library of the Commissioners of Patents.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

on BURNING AND UNBURNING, delivered at the Royal Institution of Great Britain, Christmas, 1870-71.

London: CHEMICAL NEWS OFFICE, Boy Court, Ludgate Hill, E.C.

Royal 8vo., pp. 388, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise
on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling,

A Concise View of the Law connected with
Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentee's Manual."

London: Longmans, Green and Co., Paternoster Row.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—
EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College. The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TONICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 1d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda
and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under 1 per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under 1 per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS. WIDNES, LANCASHIRE.

THE CHEMICAL NEWS.

VOL. XXIV. No. 609.

NOTES ON THE PRACTICAL PHOTOMETRY OF COAL-GAS.

By Dr. WALLACE,
Gas Examiner for the City of Glasgow.

THE following arrangement of the different parts of the photometric apparatus has been found convenient, and has been so highly approved of by those who have seen it that it is thought worthy of a brief description. The meter is not placed at the end of the photometer bar at which the gas is burned, but towards the candle end, and immediately below that part of the bar where the observations are usually made; and attached to the outlet is a three-way stop-cock with lever handle, the side branch of which is connected by a few inches of pipe with the inlet, so that the gas may be passed through the meter, or direct to the burner, as may be desired, the gas being, in either case, kept constantly burning. At the candle end, and on a level with the photometer bar, is placed a small shelf supporting the candle balance; and this is arranged so that the candles have to be moved only a few inches into the receptacle at the end of the photometer. The gas is now passed through the meter until the hand comes to zero, and the stop-cock is turned so as to pass the gas direct to the jet. The clock, which is either attached to the meter or placed immediately beside it, is also adjusted, and the candles are nearly counterpoised. At the moment when the balance turns, the operator with one hand turns the stop-cock, with the other sets the clock in motion. The candles are now placed in position, and by the end of the first half minute the operator is ready to take the first observation. The sight-box has in front of it stereoscopic lenses, so as to shorten the focus of the eyes, and make the images of the two sides of the disc more distinct, at the same time that they coalesce or overlap one another. By this means great accuracy of observation is attained, and the influence of the different colours of the two flames is entirely removed. Two circular screens of very light wood, 18 inches in diameter, strengthened by cross-bars and having in the centre openings 4 inches square, are fixed on the photometer bar, one on either side of the sight-box and about 20 inches apart, and the sight-box is provided with two side flaps of thick vulcanised india-rubber; the object of these arrangements being to prevent the possibility of any light passing to the eyes of the operator but that reflected by the mirrors in the sight-box. At the end of the tenth minute the stop-cock of the meter is reversed, and, at the same moment, the candles are extinguished; after which the operator leisurely notes the consumption of gas and the loss of weight of the candles. The advantage obtained by this arrangement is that the gas examiner does not require to move from his position opposite the meter during the whole experiment, while the meter is read off only when stationary. The stereoscopic sight-box is not an essential part of the apparatus, and requires great care in the adjustment of the lenses, but when these are carefully fixed the results obtained are highly satisfactory.

In the arrangement above described, the governor is placed immediately to the right hand of the meter (supposing the gas to be burned at the right side of the photometer) and the King's pressure gauge at the left-hand side, so that both are readily observed or corrected. The pressure at which it has been found best to burn the Glasgow gas (28 to 30 candles) is from four to five-tenths,

and the standard Cannel batswing supplied by Sugg is employed at all the testing stations. In order to prevent evaporation, the surface of the water in the meters, pressure gauges, and governors, is covered with a layer of about one-sixteenth of an inch of "intermediate" paraffin oil. This oil has a gravity of 850 to 860, and a firing-point of about 250° F., and does not affect the illuminating power of the gas, nor does it thicken by exposure to cold.

In the estimation of the sulphur in coal-gas it is usual to cut off the gas, by means of a pin acting on a lever, at 10 cubic feet, but it is more advantageous to adopt 13.7 cubic feet as the quantity, as in this case the number of grains and fractions of a grain of barium sulphate obtained represents the number of grains of sulphur in 100 cubic feet of the gas. The half of this quantity, or 6.85 cubic feet, may also be taken, but in this case the quantity of barium sulphate must be multiplied by two. The apparatus used in Glasgow is that of Dr. Letheby, with the addition of a second cylinder of about twice the capacity of the first.

The estimation of ammonia is made by means of a very simple apparatus. A tray of copper coated with paraffin, or, still better, one of porcelain, about 12 inches long by 4 wide, and 1 inch deep, has inverted in it a similar vessel 11½ inches long, 3½ inches wide, and nearly the same depth as the tray. At each end of the inverted vessel is a coupling, so that the gas to be used in the sulphur estimation can be passed through this apparatus before going to the burner. Into the tray is placed 100 measures of a test-liquid consisting of dilute sulphuric acid of such strength that this quantity would be exactly neutralised by 13.7 grains of ammonia, and water is added, if necessary, to give a depth of about a quarter of an inch of liquid. 13.7 cubic feet of gas are now passed through the apparatus in the usual manner, after which the contents of the tray are transferred to a white porcelain basin, and the tray and inverted vessel washed by means of a washing bottle, and the washings added. Some tincture of litmus is now added, and from a burette is dropped, with constant stirring, a solution of caustic potash, 100 divisions of which correspond exactly to 100 divisions of the dilute acid. When the blue colour of the litmus is restored the number of divisions consumed is read off, and the difference between it and 100 divided by 10 gives the number of grains of ammonia in 100 cubic feet of gas. The absorption of the ammonia is so perfect that not a trace can be detected by afterwards passing the gas through the ordinary bulbs filled with beads or broken glass.

ACTION OF HEAT ON PROTOPLASMIC LIFE.

By F. CRACE-CALVERT, F.R.S., &c.

THOSE investigators of germ-life who favour the theory of spontaneous generation have assumed that a temperature of 212° F., or the boiling-point of the fluid which they experimented upon, was sufficient to destroy all protoplasmic life, and that the life they subsequently observed in these fluids was developed from non-living matter.

I therefore made several series of experiments, in the hope that they might throw some light on the subject.

The first series was made with a sugar solution, the second with an infusion of hay, the third with solution of gelatine, and the fourth with water that had been in contact with putrid meat. The hay and putrid-meat solutions were taken because they had often been used by other investigators; sugar was employed, being a well-defined organic compound free from nitrogen, which can easily be obtained in a state of purity; and gelatine was

used as a nitrogenised body which can be obtained pure and is not coagulated by heat.

To carry out the experiments, I prepared a series of small tubes made of very thick and well-annealed glass, each tube about four centimetres in length, and having a bore of five millimetres. The fluid to be operated upon was introduced into them, and left exposed to the atmosphere for sufficient length of time for germ-life to be largely developed. Each tube was then hermetically sealed and wrapped in wire gauze, to prevent any accident to the operator in case of the bursting of any of the tubes. They were then placed in an oil-bath, and gradually heated to the required temperature, at which they were maintained for half an hour.

Sugar Solution.—A solution of sugar was prepared by dissolving 1 part of sugar in 10 parts of water. This solution was made with common water, and exposed all night to the atmosphere, so that life might impregnate it. The fluid was prepared on the 1st of November, 1870, introduced into tubes on the 2nd, and allowed to remain five days. On the 7th of November twelve tubes were kept without being heated, twelve were heated to 200° F., twelve to 300°, and twelve to 400° F.

The contents of the tubes were microscopically examined on the 1st of December, twenty-four days after heating.

Remarks.—The black vibrios here referred to are far more opaque than the other varieties of vibrios, and are the most important of all, as I have found them to resist not only very high temperatures, but all chemical solutions. I shall, in my paper on putrefaction and the action of antiseptics, describe the various vibrios and give drawings of them.

Hay Infusion.—An infusion of hay was made by macerating it in common water for one hour, then filtering the liquor, and leaving it exposed to the atmosphere all night, when it was sealed in the small tubes, twelve of which were used for each experiment. The infusion was made on the 4th of November, sealed in tubes on the 5th, and heated on the 7th.

The results were examined on the 1st of December, 1870, twenty-four days after being heated.

Hay infusion not heated.	Fungus matter was observed growing on the surface of the fluids in two of the tubes. On subjecting the contents of some of the tubes to examination, from 20 to 25 animalcules were observed under each field of the microscope. This kind of life resembled small dots moving energetically to and fro; 1 or 2 ordinary vibrios were also present.
Heated for half an hour at 212° F.	No fungus matter was noticed on the surface in any of the tubes. A few small black vibrios present in the original solution were also present in this.
Heated for half an hour at 300° F.	No fungus matter present, but some of the small black vibrios were still present, although in less numbers.
Heated for half an hour at 400° F.	No fungus matter observed. The fluid was filled with irregular masses of coagulated matter, and life had disappeared.
Heated for half an hour at 500° F.	No life present.
Sugar solution not heated.	There were about 30 animalcules under each field of the microscope, principally small black vibrios, 2 or 3 microzymes swimming slowly about, 3 or 4 ordinary swimming vibrios, and a few Bacteria.
Heated for half an hour at 212° F.	A great portion of the life had disappeared, no animalcules were swimming; still at this temperature had not completely destroyed life. 4 to 5 small black vibrios were observed moving energetically to and fro; 2 or 3 ordinary vibrios were also observed moving energetically in the same position of the field, that is, without swimming about.
Heated for half an hour at 300° F.	The sugar was slightly charred, but the life was not entirely destroyed, as 1 or 2 ordinary vibrios and 1 or 2 small black vibrios were observed in motion under the field of the microscope.
Heated for half an hour at 400° F.	The sugar was almost entirely decomposed; no trace of life was observed.
Heated for half an hour at 500° F.	No life observed.

T. Henry,
to give Instructions in
CHEMISTRY, particularly
AGRICULTURE, and **COMMERCE.**

The Laboratory is open daily, except on Saturday, from ten till one.

Mr. Matthews is also prepared to undertake description.

For Particulars and Prospectuses, &c.,
the Laboratory, 60, Gower Street, Bedford Square.

Gelatine Solution.—A solution of gelatine, prepared of such strength that it remained liquid on cooling, was exposed for twenty-four hours to the atmosphere. It was then introduced into the small tubes, and the tubes sealed. The solution was made on the 4th of November, the tubes sealed on the 5th, and subjected to the different temperatures on the 7th.

The fluids were examined on the 1st of December, 1870, twenty-four days after being heated.

There were 7 or 8 animalcules under each field, 5 or 6 of which were quite different to any thing observed in the other fluids. They had long thin bodies, swimming with a peristaltic motion. 1 or 2 ordinary swimming vibrios were also present; but the small black vibrios were absent.	Gelatin solution not heated.
Life seemed to have only slightly decreased, and none of the animalcules were swimming. The peculiar animalcule mentioned in the first column appeared to retain still its peristaltic motion, but not sufficient power to move across the field, a few ordinary vibrios being also observed moving to and fro.	Gelatin solution heated for half an hour at 100° F.
A very decided diminution in the quantity of life present was noticeable.	Heated for half an hour at 212° F.
No life present.	Heated for half an hour at 300° F.
No life present.	Heated for half an hour at 400° F.

Putrid-Meat Fluid.—Water was placed in an open vessel, and a piece of meat suspended in it until it became putrid and contaminated with myriads of animalcules. This fluid was placed in the usual tubes, which were sealed on the 7th of November, and heated on the same day.

The contents of the tubes were subjected to examination on the 1st of December, or twenty-four days after having been heated. (See Table in next column.)

The results recorded in the above Tables show that protoplasmic life is but slightly affected by a temperature of 212° F., and that, even at a temperature of 300° F., it is not entirely destroyed, excepting in the case of gelatine. In all the other fluids a temperature of 400° F. is necessary to completely destroy the life. These experiments, therefore, clearly show that the life found by previous experimenters in fluids which have been submitted to heat was not due to heterogenesis but to life which had remained in the fluids, as I have seen no experiment reported where the temperature to which the fluids were exposed exceeded 300° F.*

I am the more justified in making this statement, as I have repeatedly examined the contents of tubes which had been submitted to a temperature of 400° F., both im-

* It is with pleasure that I find these experiments to confirm the suggestion of Dr. Beale, in his work entitled "Disease Germs, their Supposed Origin," page 50 (which I read a few weeks ago), that "living forms might live though exposed, under certain conditions, to a temperature of 350° F."

mediately after cooling and at all periods up to thirty days, and was unable in any instance to detect the slightest trace of life.

A large quantity of life was present—namely, microzoa and several distinct species of vibrios, among which were a number of the small black ones frequently mentioned.	Not heated.
This temperature had but slightly affected the life present, the animalcules being as numerous as in the liquid not heated, and moving as usual. However, one species of very long vibrios appeared to be considerably affected, as they were much more languid in their movements.	Heated for half an hour at 100° F.
This liquor differed from all the others in being turbid and coagulated. Life was still present; and although heat had deprived the animalcules of the power of locomotion, still they retained a sufficient amount of vital force to place it beyond a doubt that life was not destroyed.	Heated for half an hour at 212° F.
The liquid was quite clear, the albumen (which is coagulated at 200°) appearing to be redissolved. A large quantity of the fluid in the tube was destroyed, but some vibrios still remained, the small black ones being the most numerous.	Heated for half an hour at 300° F.
All life had disappeared.	Heated for half an hour at 400° F.
All life had disappeared.	Heated for half an hour at 500° F.

This important result corroborates those recorded in my previous paper, and proves that the spontaneous-generation theory is not yet by any means established.

It occurred to me that it might be interesting to examine the influence on pure albumen of the putrid-meat fluids that had been heated, and note whether they still possessed the property of propagating life. A solution was prepared by mixing the albumen of a new-laid egg with pure distilled water free from life (prepared as described in my previous paper). Equal volumes of this solution were placed in six small test-tubes, which had been cleansed with hot vitriol and well washed with pure water. To one tube two drops were added of the putrid-meat solution that had been heated to 100° F., to a second two drops of that heated to 212° F., to a third two drops of that heated to 300° F., to a fourth an equal bulk of fluid heated to 400° F., and to a fifth the same quantity heated to 500° F. In the sixth, the albuminous solution, without anything added, was kept for comparison.

The tubes were sealed, and kept from the 1st of February to the 9th.

RESULTS OF EXAMINATION.

Albumen solution.	Albumen solution, with putrid-meat liquor, heated to 100° F.	Albumen solution, with putrid-meat liquor, heated to 212° F.	Albumen solution, with putrid-meat liquor, heated to 300° F.	Albumen solution, with putrid-meat liquor, heated to 400° F.	Albumen solution, with putrid-meat liquor, heated to 500° F.
In each drop 2 or 3 small black vibrios, moving to and fro.	Abundance of life.	Abundance of life.	Much less life than in the two fluids previously examined.	In each drop 2 or 3 small black vibrios, moving to and fro.	In each drop 2 or 3 small black vibrios, moving to and fro.

These results clearly show that, at the temperature of 100°, 212°, and 300° F., life and its germs had not been destroyed, whilst at 400° F. they had; for the results of the examination were in this case exactly identical with those of the albumen solution itself; and the life found was doubtless introduced in the preparation of the solution, and was not due to any life having remained in the fluids that had been heated.

Although perfectly aware of the interesting researches of Professor Melsens, proving that the most intense cold does not destroy the active power of vaccine lymph, still I thought it desirable to ascertain the effect of a temperature of 15° F. on well-developed germ-life, similar to that which had been subjected to the action of heat.

Some putrid-meat liquor, therefore, containing a large quantity of microzyma and vibrios, was subjected for twenty hours to the influence of a temperature ranging between the freezing-point of water and 17° below that point, when the ice was melted and the liquor examined. The animalcules retained their vitality, but appeared very languid, and their power of locomotion was greatly decreased.

Two hours after melting the ice the liquor was again examined, when the animalcules appeared to be as energetic as before.

ON THE ORIGIN OF THE DIAMOND.*

By the Rev. W. B. CLARKE, M.A., F.G.S.

(Continued from p. 13).

Diamonds in Brazil.

Brazil seems naturally to claim our first attention. It has been found that in a certain Brazilian rock called *itacolumite*, diamonds have been found *in situ*, and, therefore, all diamonds are assumed to have been derived in a similar way, wherever a rock imagined to be *itacolumite* exists.

In 1846, Professor Shepherd, of South Carolina (*A. S. J.*, ii., 253), announced the extensive development of the rock in that State, and he gives a figure and description of a diamond from gold washings in that formation. In Brazil, however, they occur in great numbers, in the lower *itacolumite* beds. According to Humboldt this rock belongs to the very oldest sedimentary deposits.

So far as my own observation has gone this rock does not occur in New South Wales, and even in Brazil, as I will show, diamonds are not confined to it. My friend Mr. Ulrich, late of the Victorian Survey, says the same of the sister colony, and assures me he had very good opportunities of satisfying himself by examining the Brazilian specimens at the last International Exhibition at Paris. Humboldt (*Essai Géognostique Paris*, 1820, p. 89), includes *itacolumite* in the quartz rock series parallel with his primitive clay slate.

Von Cotta places it among the crystalline schists, and

describes it as a fine-grained micaceous talcose or chloritic schist, sometimes flexible, holding occasional quartz pebbles with magnetic iron and gold, as well as diamond. According to Eschwege, it passes into *itabirite*, which belongs to the red hematitic group. Other writers include it with "mica schist," "quartz of the mica slate," and "elastic sandstone." Fleusser and Claraz consider it a "granular quartz," sometimes bearing quartz veins with pyrophyllite lime. Eschwege says it attains in Brazil a thickness of many thousand feet, ranging for hundreds of miles. The North Carolina species lies between limestone and clay slate. It is said that it occurs in Portugal, Spain, and on the Rhine. But this is doubtful. On the whole, it may be held to be a transmuted sedimentary rock—a friable quartz or sandstone.

M. Damour (*Bull. S. G. de France*, vol. xiii., 2nd series, p. 543), mentions the occurrence in Brazil of diamond bearing sand near Bahia, containing numerous minerals and ores, and states that the diamonds often contain spangles of gold in their cavities. He enumerates thirty-two mineral species, among them very minute rhombohedral dodecahedrons of garnet of a topaz yellow colour; a similar occurrence to that of Two Mile Flat, noticed by Mr. Norman Taylor, where brown garnets of the same form occur.

M. Damour suggests, in relation to the statements of M. Favre (referred to above), that the occurrence of the same minerals with diamond in different countries would throw some light on the formation. I may add that this is the principal reason which induces me now to enter so fully into this discussion.

Mr. Taylor instances as many varieties as M. Damour; but the so-called gems in the list given by the latter are confined to quartz, zircon, garnet, and tourmaline; ruby, sapphire, and corundum being absent, and euclase having been since added. The metals seem to predominate.

There is, according to M. Claussen, another solid matrix of diamond in Brazil, which he calls *itacolumite sandstone* (a secondary red sandstone), which overlies the crystalline beds, and once had an enormous development; to its denudation he attributes a considerable portion of the materials forming the mixed erratic diamond-bearing deposits; but in this he finds neither gold nor platinum. M. d'Archiac gives a very clear abstract of Claussen's remarks in his *Progrès de Géologie* (vol. ii., 379—383).

In the province of Matto Grosso, at the waterparting of the basins of the Amazon and Parana Rivers, a little south of 14° S. latitude, and at an elevation of some 1200 feet above the sea, is the diamond field of the Sierra Diamantina.

But the most important field in a geological, if not commercial view, is that which, ranging at a distance fully 900 miles S.E. of the former, stretches through the province of Minas Geraes, between 16° and 26° S. latitude, and even comes down to the coast at San Joao do Barro, where, in 1850, a chance washing of the underlying schist disclosed the presence of many diamonds. The deposit is not confined to the beds of rivers or ravines, but covers the slopes and tops of the hills. This deposit ceases exactly at the boundary of the bituminous beds of the coal measures of St. Catherine.

Is this, then, I would ask, any indication of the origin of diamond in carboniferous rocks? If so, ought not those rocks to contain diamond?

In the north part of Minas Geraes, jurassic calcareous formations cover the red sandstone, and these are, in turn, subordinate to gypsaceous marls and rock salt. Yet in the ravines, cut down to the sandstone, through the overlying beds, diamonds are found, *i.e.*, above the carboniferous formation.

Moreover, in 1839, diamonds were discovered in the psammite of Serro de Santo-Antonio de Grammao imbedded in the rock, whereas in the preceding *itacolumite* sandstone they occur between the plates of mica, just as garnets occur in mica-schist. The edges of these are

* From the Anniversary Address delivered to the Royal Society of New South Wales.

rounded, whilst in the psammite the angles are uninjured, proving that the transmutation of the sandstone into itacolumite has also affected the diamond crystallisation. For a long period the red psammite and the secondary itacolumite sandstone have been regarded as the sole matrices of diamond, whence it has been derived by the detrital erratic deposits; but since then, it has been found in the true itacolumite subordinate to the talc schists with quartz. The diamonds in the derived deposits are more numerous the nearer deposits are to the solid rocks. The detrital beds are classified according to their character.

Thus *Groupiara* is a drift not due to the present system of drainages. *Burgalho* or *Gurgalhoo* consists of superficial fragments of underlying rock. The decomposed schist of the latter is called *barro*. A sandy mass between these is spoken of as *terra*. Another bed of granular itacolumite is known as *pizarro*; but all belong to the decomposed rocks.

Cascalhao represents the sand, clay, and pebbles in the beds of rivers, torrents, lakes, and of the hollows in their courses through the solid rocks. *Tahoa-canga* or *taphan-canga* is what we call in Australia cement.

The *cascalhao* of the old watercourses goes by the name of *guipara*; that at the heads of rivers *tabuteira*; and the partly rounded pebbles of the present streams are denominated *corrido*.

The assemblage of all the minerals associated with the diamond is, according to Heusser and Claraz, from whom the last four terms are taken, called "the formation."

We learn further from these authors that though diamond belongs undoubtedly in Brazil to itacolumite and metamorphic schist, yet it is not so necessarily; for the itacolumite mountains do not always contain diamond, and in that of itacolumi itself none are found.

The minerals seem to follow a choice as to their matrix and associations. Thus anatase occurs with suboxide of iron—rutile and brookite. Euclase is found with topaz, in a whitish clay of decomposed rock.

Specular iron ore, rutile, black tourmaline, hyaline, and smoky quartz are associated. Topaz (sometimes "rotten") is abundant, but is no longer, in comparison with euclase, an object of search.

Ores of tellurium, as well as sulphur, occur in some localities. In the crystalline schists crystals of lime, arragonite, magnetic iron pyrites, copper pyrites, manganese ores, and chromate of lead are met with. Scorodite and pseudomorphs of the same also occur in the schists and in the "taphan-canga." Amethyst is found in veins in schists and gneiss, whilst chrysolite, cymophane, and green tourmaline collect in the *cascalhao* of the crystalline schist rivers.

Mr. Heuland, in 1823, exhibited to the Geological Society of London (*Transactions*, second series, i., p. 119), a diamond in *cascalhao* surrounded by scorodite (a cupreous arseniate of iron), which I do not see in M. Damour's lists, but which was found by Eschwege; and Dana says it encrusts quartz and beryl, and is found in Victoria with gold and arseno-pyrites. Of the latter mineral Mr. Ulrich gives three localities. It has not yet been found on the Cudgegong. But Schorl rock does occur there, and in the sands of Bahia, at Diamantina, in Minas Geraes; and this mineral, there called *feijao*, as well as hydrophosphate of alumina, is considered an indication of diamond.

It is stated by Mawe ("Travels in Brazil") that the mines of Cerro-do-Trio annually produced, between 1801 and 1806, to the amount of from 20,000 to 25,000 carats, and that the weight of those sent to the Treasury in Rio Janeiro was 115,675 carats.

As an encouragement to diamond seekers in this colony may be mentioned that numbers of the Brazilian crystals are so small that four or five make only a grain, so that it takes sometimes seventeen to twenty to weigh a carat. There are rarely in the course of the year more than two or three of the latter weight, and it takes two years to find one of 30 carats; so that when a negro workman found one of 17½ carats, called an *octavo*, he was crowned with

flowers, conducted in triumph to the manager, fresh clad, and set at liberty. This is reported by Malte Brun (*Précis*, vol. iii., p. 293). Dr. Thompson has ascertained that up to January 12th, 1870, 9-10ths of the diamonds at the Two-mile Flat weighed less than a carat, and that 497 together weighed 120 carat grains; but as they were different in size, the average is assumed at one carat each, the largest being 1½ carats. One, however, had been found weighing 5½ carats.

These facts are interesting as correlating, so far as is known, the prospects of this colony and those of Brazil.

To prevent reference to it hereafter, I may mention now that a new and valuable work on precious stones ("Handbuch der Edelstein") was published in Vienna last year by Dr. Albrecht Schrauf. I found a notice of it in the *Quarterly Journal of Science* for January, 1870. In it is given a formula for calculating the value of diamonds, which tested by the price actually paid for the Sancy stone (£20,000), taking the weight at 53 carats, and the price of the first carat at £15 and which is near to the theoretical result (£21,862 10s.), appears to be tolerably correct. It is this:—

$$\frac{m}{2} - (m+2)a = \text{value},$$

where m is the number of carats, and a the value of one.

I have already noticed some of the facts stated by Messrs. Heusser and Claraz.

There are one or two others which may be quoted by way of relieving the dryness of these details. But I would mention that much compact information is given by these authors, in relation to their physical and geological researches in the interior of Brazil in Dr. Petermann's "Mittheilungen" (1859, Heft. xi.)

The previous and following quotations are taken from a paper read before the Geological Society of Berlin. Herodotus, we remember, tells (iii., 102), a ridiculous story, repeated by authors as late as the sixteenth century, of gold being brought up by ants as big as dogs that guarded it when obtained, and pursued the man that took it from them; but Messrs. Heusser and Claraz tell a far more probable story of diamonds having been found among the little pebbles with which some wormlike insects cover their tubular coverings—a fact quite paralleled by the Phryganea of Auvergne, which covered their indusie with the shells of *Bulimus atomus* or a small *paludina*, forming strata which cover nearly 800 square miles, and are from eight to ten feet thick (*Scrope*, "Central France," p. 11).

There is, however, another statement of even greater interest. In the *cascalhao* are found fragments of quartz shaped like an anvil. These were used as earrings by the ancient inhabitants of Brazil. One of these ornaments was found in *cascalhao* that had never been disturbed, in a dry watercourse, covered by 18 feet of vegetable soil, on which many fine palm trees were growing. Arrow-heads and bones were also found with it. This *cascalhao* must, therefore, be comparatively recent, or the race to whom such implements belonged must have been very ancient.

According to M. Hockeder, the first diamond in Minas Geraes was discovered in the year 1827. But I believe Brazil was known to possess diamond just a century before.

The effect was much like that which takes place in Australia when a new lead is discovered. The gold workings were all deserted by what is called here "a rush," and the greatest excitement followed. M. Hockeder's memoir, though now little known, made also a stir at the time. [*Ueber des vorkommen der diamanten*]. There are other documents referred to in the *Bull. Soc. Geol. de France* (xiv., 232; i., 19; ii., 659).

Further particulars relating to the diamond beds of Brazil may be found in a paper by M. Pissis in the journal just cited (Tom. xiii).

One passage seems to bear upon certain facts observable in Australia. He says, "to these stratified rocks we must add compact diorites, which show themselves abundantly

distributed on the surface, sometimes forming long lines of hills, sometimes simple *mamelons* in which the matter appears to have been poured out in the manner of basalts, producing long sheets which cover the last beds of the limestones, whether siliceous or schistose." He then goes on to speak of the sandstones which underlie the limestones, and which are to be regarded as the true matrix of the diamond. "Thus, of all the rivers of the province of St. Paul those only which flow over the sandstones are diamond bearing." And instancing the Rio Guarahi, he says it leaps over the escarpment, where it forms several cataracts, cutting through the various beds of sandstones and psammities, and it is only below the cascades that you begin to find diamonds, a similar remark to that of M. Claussen in relation to the coal measures.

Other facts worthy of mention may occur in Captain Burton's work on the "Highlands of Brazil," but as I have never yet seen a copy of that work, I have not referred to it.

(To be continued).

ASSAY OF GOLD AND SILVER,

AS PRACTISED AT THE LABORATORY OF THE SCHOOL OF MINES, COLUMBIA COLLEGE.

By T. M. BLOSSOM, E.M.

(Continued from p. 16).

The Charge.

THE weight of ore taken for an assay depends upon its supposed richness or poverty, since it is required to obtain finally a bead of precious metal of convenient size for weighing, and, at the same time, neither too large for cupellation (*vide* Cupellation) nor so small as seriously to affect the calculated results, through losses sustained in the assay. As a rule, it is usual to take one-third assay ton for silver ores, and one, two, or four assay tons for gold ores.

A special method will be given for galena. All other ores require the following reagents:—Litharge, carbonate of soda, and one of the reducing agents, argol and charcoal, or an oxidising agent, as nitre, with invariably a cover of salt one-quarter to half an inch in depth. Borax, silica, and other reagents are very useful at times, but no general rule can be given for their employment. This matter must be left to the judgment of the assayer, guided by the known properties of the reagents and by the composition of the ore. It is well, in this connection, to bear in mind the principle that for basic impurities, an acid flux is needed, and for an acid gangue a basic flux. As a rule, employ a weight of litharge twice that of the ore, and of carbonate of soda, the same as of ore. These proportions also may be modified to advantage, according to the composition of the ore. The proportion of nitre, or of reducing agent, depends upon the reducing power of the ore, hence it is variable in every case. These reagents are added to control the size of the lead button.

Size of the Lead Button.—There are two limits to the size of the button: (1) it must be large enough, or, in other words, enough litharge must be reduced throughout the mass to collect all the precious metal, and, at the same time (2) there should not be a useless excess of lead, which would occasion loss of silver in the subsequent cupellation.

These two conditions cannot always be fulfilled, but in this case the latter must be sacrificed. It has been found that a button of 15 to 20 grammes is the best size for a weight of ore from one-third to four assay tons. This is also a convenient size for a cupellation. A button that is too large for cupellation can, however, always be reduced in size by scorifying.

These requirements necessitate, in many instances, a preliminary assay of the ore to determine its reducing

power. The reducing power of an ore is due to the presence of sulphur, arsenic, antimony, zinc, &c., but generally to sulphur contained in pyrites, &c.

Preliminary Assay of Ore.

Charge.	Ore	..	..	..	2	grms.
	Litharge	..	..	25	..	
	Carb. soda	..	..	10	..	
	Salt	..	..	..	Cover.	

A duplicate assay need not be made.

Warm the crucible before placing it in the fire, which should be perfectly bright and should be urged to effect complete fusion in the shortest possible time. When the contents of the crucible are in quiet fusion, it must be withdrawn, to prevent farther reducing action of the furnace gases. Tap the crucible gently, and when cold break it open.

Three cases may arise here. Two grammes of ore may yield—

1. No lead, or less than three grammes.
2. Three grammes lead.
3. More than three grammes.

The reducing power is stated thus:—2 grms. ore = — grms. lead. Let us suppose that we shall take for the regular assay $\frac{1}{4}$ A. T. of silver ore and that the reducing power is found to be 2 grms. ore = 1.5 grms. lead: $\frac{1}{4}$ A. T., or 10 grms. (about) ore will in this case reduce 7.5 grms. lead, and as the required button is 15 grms., we must add enough argol, or charcoal, to reduce 7.5 grms. in addition; taking argol as 8.5, we shall require $7.5 \div 8.5$ grms. or 0.882 grms., say 1 grm., or charcoal $7.5 \div 28 = 0.268$, say 0.3 grm.

If the reducing power correspond to the third case, a similar calculation will indicate how much nitre is needed to oxidise part of the sulphur, arsenic, or other reducing agent, and thus prevent the reduction of a button larger than 15 grammes. In the second case, ten grammes of ore would reduce a button of 15 grms. and neither argol nor nitre would be required.

The character of slag obtained in the preliminary assay may also suggest some modification of the regular charge. If it be earthy, for instance, we would add borax glass or silica. Experience will often enable the assayer to judge of the reducing power with sufficient exactness, without an extra assay. Cases will arise, however, in which he must make a preliminary assay, or roast the ore, and it is always best to roast when there is a large amount of sulphur in the ore. He will then have an ore of no reducing power.—(Case I.)

Ores to be Roasted.

Ores containing a large amount of sulphur or arsenic, antimony or zinc, should always be roasted. In the former case, if the ore be not roasted, there will be danger of the formation of oxysulphurets, which are very fusible, but are not decomposed even at a white heat, and enter the slag carrying silver with them. A large quantity of nitre also subjects the contents of the crucible to the liability of boiling over; even should this mishap not occur, the great evolution of nitrous and sulphurous vapours puffs up the mass throughout the crucible, and the globules of lead afterward reduced may be left adhering to the sides, not being washed down by the retreating charge. Arsenic and antimony produce arseniates and antimoniates, which carry silver into the slag. Zinc increases the loss of silver by volatilisation and also in the slag.

Roasting the Ore.

The ore may be roasted conveniently in a cast-iron pan over the crucible furnace. There ought to be a hood over the furnace, to carry off the fumes of sulphurous, arsenious, and other acids. The pan should be covered with a coating of red ochre, or, still better, of chalk. The former is put on wet with a brush. An excellent even coating of the latter may be obtained by

making a chalk paste, of proper consistence, in the pan, and turning with the hand so as to spread the paste while the pan is being held over the fire to dry. The coating prevents a loss of ore and injury to the pan through the sulphides attacking the iron.

The weighed sample must be spread over the pan and stirred with a bent wire until all danger of fusion is past. The pan must be heated gradually at first, not above a dull red heat for some time, and may be brought, finally, to a full red, or higher heat. Too high a heat at the outset might cause the fusion of sulphides and the formation of mattes troublesome to roast. A rapid disengagement of arsenic, antimony, or zinc, would cause, also, a mechanical loss of silver, by carrying it off in their vapours. Should fusion take place, it is better to weigh out a fresh portion of ore and roast again with more care. If this be not done the fused portions must be pulverised in a mortar and re-roasted. Generally, in roasting sulphides, the operation may be considered finished when, after keeping the pan at a full red heat for some time, no more fumes of sulphurous acid can be perceived. As there is danger, however, of the formation of sulphates, especially if copper pyrites be present, it is best always to mix some carbonate of ammonia with the ore, after the fumes have ceased, and to cover the pan. The ore is thus confined in an atmosphere of carbonate of ammonia, which decomposes the sulphates with formation of volatile sulphate of ammonia.

Arsenic and antimony require the addition of fine charcoal, to reduce any arseniates and antimonites that may have been formed during the roasting. Care must be taken to burn out all the charcoal.

If the ore contain a very fusible sulphide, as antimony-glance or galena, it may be mixed with some fine sand previous to roasting.

The roasting of ores may also be done in the muffle in an earthen saucer.

Fusion.

The charge prepared according to the foregoing directions is thoroughly mixed and placed in a crucible, which it should not more than two-thirds fill. A hot fire should be employed, and the crucible removed when complete fusion has taken place. This ought to require from twenty to twenty-five minutes. The crucible is tapped, as usual, and broken when cold.

b. Scorification Assay.—

The reagents necessary for a scorification assay are test-lead and borax glass. The ore is mixed with these in suitable proportions, the mixture put in a scorifier and fused in a muffle. The operation affords an alloy of lead with the precious metals, and a slag composed of litharge with the impurities and gangue of the ore. The assay might be made with lead only, but it is advantageous, as will appear, to add some borax. There will be required of lead only enough to render the slag liquid and to furnish lead for the button. The proportions of both lead and borax will vary, and should be greater in proportion as the gangue and metallic oxides are more difficult of fusion. The following table exhibits the proportions found by experience to be best adapted to the different gangues. The proportions are referred to one part of ore.

Character of Gangue.	Parts Test-Lead.	Parts Borax.
Quartzose	8	
Basic ($\text{Fe}_2\text{O}_3, \text{Al}_2\text{O}_3, \text{CaO}$), &c.	8	0.25-1.00
Galena	5-6	0.15
Arsenical	16	0.10-0.50
Antimonial	16	0.10-1.00
Fahlerz	12-16	0.10-0.15
Iron pyrites	10-15	0.10-0.20
Blende	10-15	0.10-0.20

No preliminary roasting is required. As in the crucible assay, the weight of ore taken depends very much upon

its richness, but is generally a third, sixth, or tenth of an assay ton. If one scorifier will not contain the charge, it is best to weigh equal fractional parts for the number required, rather than to weigh the whole charge and roughly divide it between the scorifiers. In case of an accident to one of the scorifiers, the known loss can easily be restored, if the former course be followed. The exact parts that lead and borax perform in scorification can be understood best from a description of the operation in detail.

Three distinct periods may be noted in the working:—

1. Roasting; 2. Fusion; 3. Scorification. A strong heat is maintained, at first, in order to melt the lead. This is effected by closing the muffle and regulating the draught. As soon as the lead is fused the muffle is opened, and the ore is seen floating upon the surface of the lead.

1. The roasting now commences, and is continued at a moderate heat until no more fumes are seen, and the ore has disappeared.

2. The heat should now be raised in order to fuse thoroughly all the material in the scorifier. When the fusion is complete, clear white fumes of lead may be seen arising from the scorifier, there is an intermittent play of colours across the bright surface of the lead, and the slag produced encircles the metallic bath like a ring. The borax plays an important part just here, by giving liquidity to the slag, thus permitting it to be thrown to the side as fast as formed, exposing a clear surface of lead for oxidation. If borax be not added and the ore contain a difficultly fusible gangue, the scorifier will float in detached masses over the lead, impeding the oxidation, until sufficient litharge has been formed to give it liquidity.

3. When the fusion is complete, the heat may be lowered and the third period of scorification continued until the ring of slag, which is continually growing smaller, close over the residue of metallic lead. The heat should again be raised, to liquefy the slag and allow the metallic lead to settle, after which the scorifier is removed from the furnace. If the button is wanted immediately for cupellation, the contents of the scorifier may be poured into an iron or copper mould coated with red ochre. It is thus soon cooled. Otherwise allow the contents to solidify in the scorifier, and break this for the button when cold. Hammer the button as usual.

The whole assay occupies about thirty-five minutes.

In making the charge, it is customary to mix the ore with a part of the test-lead and with borax, and to cover this in the scorifier with the rest of the lead. This will prevent loss of ore prior to fusion. Too much borax should not be added at first. If a large amount is needed, it is better to mix only a portion with the ore, one gramme, for instance, and to introduce the rest wrapped up in paper, as needed during the operation. Some of it may be reserved for the final heating after the lead is slagged over. If too much were added at first, the lead would be slagged over before the necessary reactions had taken place.

The Lead Button.—The lead button submitted to cupellation must be malleable and of the proper size for the cupel. A good cupel will absorb its own weight of litharge, but it is better to use a cupel one-quarter to a third as heavy again as the lead button. The cupels in ordinary use weigh about 18 grammes, hence a button of 12 to 15 grammes is the proper size for them. If the button be too large it may be reduced in size by scorification. In case of doubt it is better to scorify, since there is less loss in this operation than in cupellation. A brittle button may be due to the presence of sulphur, arsenic, antimony, zinc, or litharge. In either case it must be scorified before cupellation, and with test-lead if necessary. If the button contain copper it must be scorified until no more copper can be seen on hammering out the button. If nickel be present the button cannot be cupelled. This, however, will occur but rarely.

3. *Cupellation.*—

The lead button obtained by the foregoing operations is next cupelled. This operation is similar in many respects to scorification, but differs from it in that the scoriae formed are absorbed entirely by the cupel, leaving a pure bead of the precious metals. This property of the absorption of scoriae is an indispensable condition in cupellation, so that, unlike scorification, it is limited to a few substances capable of being absorbed by the cupel. The oxides of lead and bismuth alone can be absorbed in a state of purity, but they can carry along with them certain proportions of other substances which, by themselves, would form infusible scoriae. It is thus that we are enabled to get rid of small amounts of copper, iron, arsenic, &c., remaining in the lead button. Bismuth is seldom, if ever, used for this purpose. The proportion of lead required to carry off the different impurities varies according to circumstances. In the case of lead buttons from an assay, there is always an excess of lead, if they have been properly purified. Other cases will be treated under the head of Assay of Alloys, where the necessary tables will be given.

The operation of cupelling a lead button is conducted as follows:—

The cupels must be carefully dried before use, and must be free from cracks, which would cause a loss of precious metal. The bottom of the muffle should be covered with sand, to prevent injury to it in case of the upsetting of a cupel. A cupel having been selected, it should be wiped carefully with the finger, and all extraneous matter blown out. It may then be placed in the muffle. Before the introduction of the lead button, the muffle should have attained a reddish-white heat, and the cupel should be of the same temperature. This being attained, the button is placed in the cupel with a pair of forceps, gently, so as not to injure it. The muffle should now be closed, either by a door or by a piece of lighted charcoal, to bring the fused button to the same temperature. This done, the muffle is opened and air allowed to enter; the button, which at first appears bright and uncovered, is soon covered with a film of oxide moving in luminous patches over the surface, and being continually thrown toward the edge, where it is absorbed by the cupel. White fumes of lead arise, and the button is surrounded by a ring of the absorbed litharge, which continually widens until it reaches the edge of the cupel. The button thus gradually diminishes in size by oxidation and absorption, and becomes more convex; the luminous patches become larger and move more quickly; and when, finally, the last of the lead is absorbed, the button appears to revolve rapidly on its axis, becomes very brilliant, and is suffused with all the tints of the rainbow; the movement is suddenly checked, the button becomes dull for a few instants, and then presents the appearance of the pure precious metals. The latter part of the operation is called the "brightening" of the button. Should the bead be large, and composed, in great part at least, of silver, it must be removed slowly and gradually from the furnace, to prevent loss by "spitting," which might happen if the cupel were removed at once from the muffle. When a cupel is withdrawn directly after brightening, the button is liable to be covered by mammillated and crystalline protuberances, and is then said to have "vegetated" or "spit." Portions of the metal are sometimes thrown off and lost. Whatever the cause may be, this does not occur if the button be withdrawn gradually, so as to permit a slow and gradual cooling. In case the bead be very large, say 100–300 milligrammes, it is well to cover it with a hot cupel, which will retard the cooling and prevent the loss of small particles that may be thrown off despite all care. If the bead is not larger than the head of an ordinary pin, the danger of vegetation is slight, and no great precautions need be taken in its removal.

Two causes have been assigned for this "spitting." One is that molten silver absorbs oxygen from the atmosphere and gives it up at the moment of solidifying, thereby

occasioning the vegetation. Another is, that by rapid cooling a crust is formed on the outside, which contracts upon the liquid interior and is broken, forcing the molten metal through the rents thus made. The latter is simple and plausible; the former is supported, apparently, at least, by elaborate experiments.

It is well to raise the heat of the furnace just before the brightening, or to push the cupel into a hotter part of the muffle, in order to aid the brightening and get rid of the last traces of lead, which are somewhat difficult to remove. The button should also, for the latter purpose, be heated strongly a few seconds after brightening.

Silver is sensibly volatile at a high heat; the loss of gold is slight, and may be disregarded. In the assay of ores this loss need not be considered, but in bullion assay a correction is necessary, for which a table will be given under Assays of Alloys. The loss of silver increases with the temperature, but we must avoid, in cupellation, the two extremes of a high heat and quick work and a low heat with prolonged work. Of the two extremes the latter is worse. The following are indices of favourable working:—The muffle is reddish-white, the cupel is red, the fused metal very luminous and clear, the lead fumes rise slowly to the top of the muffle, and the litharge is completely absorbed by the cupel.

The heat is too great when the cupels are whitish, when the fused metal is seen with difficulty, and the scarcely-visible fumes rise rapidly in the muffle.

The heat is too low when the fumes are thick and fall in the muffle, and when the unabsorbed litharge is seen forming lumps and scales about the button.

The degree of heat should bear some relation to the richness of the alloy, and may be greater according as the lead is poorer in silver. By bearing this in mind the assayer may often hasten the operation without detriment to the assay. The draught of air through the muffle must also be regulated. Too strong a current cools the cupel and oxidises the lead faster than it can be absorbed, thus endangering the assay. Too slow a current prolongs the operation and increases the loss by volatilisation. In ordinary work this matter, however, occasions very little trouble.

It happens sometimes that the material in the cupel becomes solidified in the midst of an operation, stopping all farther action. This disaster is called the "freezing" of the button, and is occasioned by the following conditions; a production of litharge more rapidly than it can be absorbed by the cupel, and infusible scoriae, due to a cold furnace, or to an excess of foreign oxides. In either case the scoriae gradually extend over the surface of the button until it is entirely covered, when farther movement ceases. This disaster may sometimes be prevented or remedied by raising the heat of the muffle; if this fails, or if the accident be due to foreign oxides, an addition of pure lead must be made to the assay; in either case, the results are unreliable.

An assay that has *passed* well, furnishes a bead well rounded and clear, crystalline below, and readily to be detached from the cupel. If the bead contain lead, it is brilliant below, and does not adhere at all to the cupel. If the bead exhibits rootlets passing down into the substance of the cupel, the results are inaccurate.

(To be continued.)

MISCELLANEOUS.

Stevens's Institute of Technology, Hoboken, N.J. —The first session of this institute, of which Professor Henry Morton is the President, will commence on the 26th of September. Apparatus, &c., already purchased amounts to upwards of £5000.

Trial of the Pyx of the Mint.—On Tuesday, July 18th, this ancient and interesting trial was held at the Goldsmiths' Hall, the proceedings, commencing at nine o'clock, a.m. The following is an extract from the verdict of the

July:—"We then assayed the six sovereigns, and three half-sovereigns separately, and we found the millesimal fineness of such sovereigns to be 916·9, 916·7, 916·7, 916·8, 916·7, 916·7 respectively, and the millesimal fineness of such half-sovereigns to be 916·6, 916·6, 916·5 respectively." The true standard of gold is 916·66 parts of fine gold in 1000 of alloy; therefore the result of the trial is truly wonderful, and reflects great credit on the responsible officer, Mr. W. Chandler Roberts, the chemist to the Mint. The bulk of the silver coins agreed exactly with the standard trial plate, although the law allows a variation of eight parts in the thousand.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 26, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Memoir on the Transport of some Salts by Electrical Discharge.—Dr. Becquerel.—This lengthy essay treats on some phenomena observed by the author while experimenting on the effect of only moderately strong electrical discharges when certain chemical compounds are placed in the route of the electric current. As results from these experiments, the author finds that the undermentioned salts and other chemicals are transported by electrical discharges in the direction from the negative electrode to the positive electrode, but not again the reverse way. These salts and substances are ferricyanide of potassium, bichromate of potassa, chloride of barium, chloride of sodium, chloride of potassium, sulphuric acid, phosphoric acid, chloride of ammonium, and protochloride of iron. The following are among the substances which are not transported by any electric current, whatever its direction:—Chloride of cobalt, chloride of platinum, nitrate of silver, caustic potassa, and sulphate of potassa.

Relation existing in the Sun between the Faculae, Protuberances, and Corona.—Rev. A. Secchi, S.J.—A lengthy letter by the eminent savant communicating his latest discoveries on the physical constitution of the sun. This preliminary notice is to be followed by a complete essay on this subject.

Experimental Researches on the Preparation and Properties of the Propyllic and Butylic Chlorides.—J. Pierre and E. Puchot.—This very lengthy memoir describes exhaustively the various methods of preparation employed by the authors for obtaining: (1) Propyllic chloride, C_3H_7Cl , a liquid which, in a pure state, is colourless, very mobile, exhibiting a not unpleasant, yet somewhat alliaceous (garlic-like), odour, and boils at $46^{\circ}5$; its density at 0° is 0.9156 , and at 39° 0.8671 . (2) Butylic chloride, C_4H_9Cl ; also a liquid which, in many of its properties, is similar to that just alluded to, but boils at 69° , and has at 0° a sp. gr. of 0.8053 . The authors are engaged in making further researches on some of the products of decomposition of these fluids, only briefly alluded to in this paper.

Researches on Animal Amidon, a Starch-Like Substance.—C. Dareste.—This paper is a physiological essay on the occurrence of a microscopically-small granular substance which has been observed by the author to be present in the yolk of eggs, the ovary, liver, and other organs of animals, and which substance, in many of its chemical and physical properties, exhibits a similarity to starch.

Second Memoir on the Heat Evolved by the Combustion of Magnesium, Indium, Cadmium, and Zinc.—A. Ditt.—An algebrico-physical memoir.

This number contains also several important meteorological papers, and an interesting account of the fate of the balloons started from Paris during the siege of that city by the Germans.

July 3, 1871.

This number opens with a very lengthy and highly valuable memoir on the—

Heating and Ventilation of the Palace of the Corps Législatif during the Session 1869-70.—General Morin.

The other original papers and memoirs relating to chemistry and collateral sciences are—

Reactions which take place between Oxide of Carbon under the Joint Action of Metallic Iron and the Oxides of that Metal.—L. Gruner.—Reserved for translation and full reproduction.

Monochlorides of the Bibasic Acids.—L. Henry.—This essay, however valuable in a scientific point of view, is not well suited for any useful abstraction, owing to the large number of formulae absolutely required for the proper elucidation of the subject.

Properties and Industrial Manufacture of Nitroglycerine.—P. Champion.—From this very lengthy memoir we quote the following particulars bearing upon the properties of nitroglycerine, which is absolutely insoluble in water, but soluble, in all proportions, in ether, methylic alcohol, and ordinary alcohol (but, as regards the latter, only at a temperature above 50°). Nitroglycerine is somewhat volatile, without decomposition, above 100° , and is not liable to spontaneous decomposition when pure. When exposed for several hours to a temperature of -15° , nitroglycerine becomes thick, but not solid; while a prolonged continuation of cold of only -2° freezes this body, converting it into a crystalline mass. Fuming nitric acid dissolves, but also decomposes this fluid; and the same effect is produced by concentrated sulphuric acid, and also by the mixture of sulphuric and nitric acids employed for the preparation of nitroglycerine. This latter fact explains the deficiency of the theoretical quantity (246) which is obtained in the preparation of nitroglycerine from 100 parts of glycerine. Nitroglycerine is also decomposed by aqua regia, by ordinary nitric acid at 50° , and by a concentrated solution of caustic soda, a nitrate of that base being formed. The author's experiments prove that pure nitroglycerine boils, but does not explode violently, at 185° ; volatilises slowly at 194° , rapidly at 200° ; deflagrates violently at 217° ; detonates difficultly at 241° , but violently and completely at 257° ; at a higher temperature the detonation is less violent, and at 287° is accompanied by flame. At low red heat, nitroglycerine assumes the spheroidal state, and is volatilised without detonation. While nitroglycerine detonates with great violence by a smart blow, it is not affected by electrical shocks.

Iodo-Chromate of Potassa.—P. Guyot.—The author describes, at some length, the mode of preparation of the salt alluded to, $2(CrO_3)IK$, or—

stating that this salt usually contains an excess of iodine, and is decomposed in contact with water. The best mode of preparation of this salt, so as to obviate excess of iodine and obtain the salt crystallised, is to heat gradually, but without ebullition, a saturated solution of iodic acid with pulverised chromate of potassa, to be added by small portions at a time, and to cool slowly the porcelain vessel wherein the operation is performed.

Xanthine, and its Detection in Vesical Calculi.—G. Lebon.—A physiologico-chemical paper. Xanthine, $(C_{10}H_8N_4O_6)$, is a substance found in very small quantity in urine, but very rarely met with in vesical calculi.

Moniteur Scientifique, Nos. 347 and 348 (double number), June 1 and 15, 1871.

This number opens with an exhaustive essay on the—

Treatment to be Adopted in Cases of Adder Bites.—Dr. A. Viaud-Grand-Maraix.—This essay contains a large amount of useful and well-digested matter. Fortunately, in the United Kingdom poisonous snakes are rare; whereas, in many parts of France they are so abundantly met with as to make it necessary for the authorities to pay a premium of from 1 to 2 francs for every killed snake exhibited and given up during a certain period of the year.

The original papers bearing upon chemistry and collateral sciences are the following:—

Separation of Silver from Argentiferous Lead.—Dr. E. Kopp.—This lengthy memoir treats first on the process of extracting silver from lead by means of zinc, and contains next a description of M.M. Rothschild's large works established at Havre for the purpose of refining every month some 500 tons of Spanish lead by means of zinc, followed by descriptions of similar works established in the Harz and Upper Silesia, and, lastly, the description of the works of M.M. Herbst Bros., at Call. This excellent essay is too lengthy to admit of any useful abstraction, and, unfortunately, also for translation in full.

Use made of Finely-Divided Metallic Tin.—Dr. E. Kopp.—Very finely-divided tin is prepared by the decomposition of a solution of a proto-salt of tin, by means of metallic zinc, in the following manner:—Into some 15 to 20 cylindrically-shaped earthenware jars capable of containing 12 litres are poured from 8 to 10 litres of a solution of chloride of zinc at a density of from 10° to 15° B. (sp. gr. 1.070 to 1.109), to which are added from 40 to 70 grms. of tin-salt (protochloride of tin), after which stout pieces of sheet zinc are placed in this liquid. The reduction of the tin takes place gradually; and as soon as the reaction is finished the liquid is cautiously poured on a fine silk sieve. The filtrate is again used, and the metallic tin is first washed by decantation, and the very finely-divided metal is next collected on a filter, washed once more with distilled water, and afterwards dried. The substance thus obtained is chiefly used in the production of the so-called argentine printing, either upon silk or fine cotton fabrics (fine muslins and mousselines de laine), the very finely-divided metal being fixed either by means of albumen or an ammoniacal solution of caseine. After printing and dressing, the fabric, in order to give the metallic silvery gloss, is hot-pressed. A very large quantity of this finely-divided tin is also used in the manufacture of surface-metallised paper, and for the purpose of ornamenting gilt picture-frames.

Method of Rendering Wooden Taps Impervious for Liquids and Preventing their Cracking.—Dr. E. Kopp.—The taps are placed in molten paraffin heated to from 110° to 120° ; by this means

the water is eliminated from the wood, and the wood becomes thoroughly impregnated with paraffin. The taps are not removed from this bath until all the aqueous vapour has been expelled and left, after the removal of the vessel from the fire, in the molten liquid up to the very moment the paraffin begins to solidify. Wooden taps thus prepared are very durable, do not become soaked with liquids, keep very tight, and are not liable to become mouldy. The excess of paraffin is wiped off with care, and the taps are next rubbed clean with a piece of flannel.

Animal Charcoal, and its Use in Sugar Refining.—A. Vivien.—This valuable essay contains a very large amount of useful practical matter, but the paper is too lengthy to admit of any useful abstraction.

Testing by means of the Blowpipe.—F. Jean.—The author states that sulphuret of sodium is one of the best blowpipe tests, if used in the following manner:—First, a bead is made with borax and the substance to be tested, and the bead, having been made very fluid within the reduction-flame, there is added to it some dry and pulverised polysulphuret of sodium, and the bead again heated in the reduction-flame. If the substance under investigation can form a sulpho-acid, there will be formed a soluble sulpho-salt and a clear bead; but when no such salt can be formed, with lead, for instance, an opaque bead will be formed. Iron, lead, bismuth, nickel, cobalt, palladium, thallium, silver, copper, uranium, &c., fused in a bead of borax, to which, afterwards, sulphuret of sodium is added, will yield a black or brown-coloured opaque bead; zinc yields a white opaque bead; cadmium, while yet hot, scarlet-red, and yellow after cooling; manganese a dirty chestnut-brown; gold and platinum, a clear, transparent, mahogany-brown bead; tin, a clear, transparent, yellowish-brown bead; chromium, a green bead; arsenic and antimony, colourless clear beads; vanadium and iridium, blood-red beads; a slight excess of the sulphuret of sodium is required, and the bead should be heated carefully, but steadily, and with a good blast in the reduction-flame.

La Revue des Scientifiques de la France et de l'Etranger,
July 15, 1871.

This number does not contain any original papers on chemistry and collateral sciences.

Polytechnisches Journal von Dingler, first number for June, 1871.

The original papers and memoirs relating to chemistry and collateral sciences contained in this number are—

Phosphorus Bronze.—MM. Montefiori-Levy and Kimtzel.—This paper treats on a subject which (as proved, also, in the appendix added to this paper by the editor of this periodical) has been frequently a subject of research and of trials on the large scale—to wit, the addition of a certain proportion of phosphorus to either copper alone, or to an alloy of copper and tin with or without any zinc. It appears that the authors have hit upon a plan for manufacturing an alloy, of which phosphorus is one of the constituents; but this paper does not give any information on the chemical composition of this alloy, which appears, however, from experiments made with it, to be exceedingly well adapted for the construction of some parts of machinery, and also for the purpose of making carbine and rifle barrels.

Separation of Oxide of Iron from Oxide of Uranium, and the Estimation of Phosphoric Acid by means of Uranium.—H. Rheineck.—Reserved for full translation.

Best Means of Improving Fireclays, so as to render them more Suited for the Manufacture of Glass, as well as for General Purposes.—Dr. C. Bischof.—The contents of this paper altogether bear upon matters of practical detail in respect of the manufacture of fireclay articles. Among the means of rendering these less readily fusible, and acted upon by the constituents of glass, the author mentions the judicious application of the powder of broken seggars and glass pots.

Flückiger's Reactions of Water-Glass.—Dr. Thüssing.—In order to understand the contents of this paper, we refer our readers to *CHEMICAL NEWS*, vol. xxii., pp. 239 and especially 263, where Dr. Flückiger's experiments are quoted. The author of this paper, having repeated some of these experiments, states that a chemical action between the neutral salts of the fixed alkalies and water-glass, whereby free silica should be separated, is not at all likely to occur, but that it is more probable that these salts will behave with water-glass in a manner akin to their behaviour with soaps, and that, consequently, the precipitate, instead of being free hydrated silica, is an alkaline silicate. This the author has proved by experiment, for, on treating, according to Dr. Flückiger's plan, a solution of water-glass with ammonia, the gelatinous precipitate, properly washed by means of Bunsen's pump, was, on analysis, found to consist, in 100 parts, of—Silica, 79.38; soda, 20.62; corresponding to a formula, $4\text{SiO}_2 \cdot \text{Na}_2\text{O}$. Water-glass (silicate of soda), treated with nitrate of soda, yielded a precipitate consisting, in 100 parts, of—Silica, 53.81; soda, 13.90; water, 32.29. Formula, $4\text{SiO}_2 \cdot \text{Na}_2\text{O} \cdot \text{OSH}_2\text{O}$.

Estimation of the Value of Oil-Seeds.—Dr. H. Vohl.—This paper is an appendix to the author's former paper on this subject (see *CHEMICAL NEWS*, vol. xxiii., p. 287). From the contents of the paper now before us, we learn that the average quantity of oil contained in the following seeds is, in 100 parts—Linseed, 27.133; hemp-seed, 25.875; poppy-seed, 49.403; walnuts, 50.06; almonds, 52.416; seeds of grapes, 17.956. The a. gr. of these oils, in pure state, at 15° is—For linseed oil, 0.9247; hemp-seed, 0.9265; poppy-seed, 0.9217; walnut oil, 0.9264; almond oil, 0.9180; grape-seed oil, 0.9222. There are added to this paper some particulars on the mode of conducting the

quantitative extraction of the oils from the seed, and a very useful tabulated index for calculating the quantity of oil contained in the oil-bearing seeds according to the specific gravity of the Canada oil extract of the seeds at 15° . By Canada oil is meant a kind of petroleum spirit of 0.680 sp. gr.

Although not strictly belonging to the subjects usually treated of in our journal, we think it may interest some of our readers to have their attention called to—

General Police Regulations concerning the Construction and Measures for Safety of Steam-Bollers for the North-German Confederation.—This document, clearly and concisely written, is a valuable contribution to what is properly and tersely termed *Administration de la sûreté et salubrité publique*.

Malleable Iron Gas Retorts.—Dr. Dingler.—The author states that such retorts, forged at the ironworks at Kaiserslautern (Bavaria), are now in use at several large German gasworks, inclusive of that newly built at Frankfort-on-the-Maine, and that these retorts, besides being far less heavy, are also far more durable than cast-iron retorts.

Contamination of Chloride of Barium with Hyposulphite of Baryta.—Dr. Wittstein.—The author found this impurity in the chloride of barium employed in his laboratory; he explains the presence of this substance in chloride of barium in the following manner:—When chloride of barium is prepared from sulphuret of barium, and this latter not quite completely decomposed by hydrochloric acid, any undecomposed sulphuret of barium is gradually converted into hyposulphite of baryta, which, unless the chloride is purposely re-crystallised, remains mixed with the chloride.

Application of Neutral Water-Glass (Silicate of Soda or of Potassa) for the Purpose of Washing Wool.—Von Baerle and Co.—This paper mainly states that neutral water-glass (as purposely prepared by the parties just named), 1 part, and 40 of water, heated to from 50° to 57° , is one of the best and also cheapest means of washing wool. The same substance (viz., this water-glass) is recommended instead of soda and soap for domestic washing purposes.

Tannin as a Substitute for Hops in certain kinds of Beer.—Dr. Dingler.—The use of hops in brewing is partly necessitated by the clarifying action it exercises. Now the author states that 15 grms. of tannic acid have in that respect the same effect as 1 lb. of hops, and that, therefore, where it is desired to brew a sweet-tasted beer, hops may be replaced by tannin previously dissolved in from eight to ten times its weight of water.

American Journal of Pharmacy, July, 1871.

Besides papers and memoirs more directly relating to pharmacy, this number contains the following original ones relating to chemistry:—

On Cundurango.—Dr. T. Antiell.—The contents of this paper describe some experiments made by the author with samples of a vegetable product, wood and bark, obtained from Loja, a province of the State of Ecuador, known locally as *cundurango*, and stated to be a remedy of great value in cancer, fungus hæmatodes, and constitutional syphilis. The bark (the medicinal virtues of the product appear to be therein contained) was found to consist of—Water at (100°) , 8 per cent; mineral matter, 12 per cent; vegetable substance, 80 per cent; this latter being separable into—Fatty matter, soluble in ether and partially in strong alcohol, 0.7; yellow resin, soluble in alcohol, 2.7; gum and glucose from starch, 0.5; tannin, yellow and brown colouring matters (extractive), 12.6; cellulose, lignin, &c., 63.5; no crystal, alkaloid, or active principle was found, and no volatile oil. The botanical characters of the cundurango-producing tree or shrub are unknown.

Examination of Sub-Nitrate of Bismuth.—J. D. Owen.—The author, having been requested to make an examination of the substance just named—the *bismuthum hydrico nitricum* of the Pharmacopœia; formula, $4\text{BiO}_3 \cdot \text{NO}_2 \cdot \text{H}_2\text{O}$ —tested four samples, the composition of which was found to be as follows:— $\text{BiO}_3 \cdot \text{NO}_2$ —79.07, 73.44, 76.92; $\text{BiO}_3 \cdot \text{H}_2\text{O}$ —18.33, 21.24, 23.58, 15.48; $\text{BiCl}_3 + 2(\text{H}_2\text{O}, \text{BiO}_3)$ —1.36, 5.94 (two other samples, only a trace); AgCl —0.37 (other three samples, only a trace); arsenic in sil, only a trace; water uncombined—0.74, 1.69, 2.68, 1.68.

Synanthrose, a New Carbo-Hydrate.—O. Popp.—From dahlia tubers the author has prepared a substance which he calls synanthrose, a white, amorphous, deliquescent substance, readily soluble in water and dilute alcohol, insoluble in ether, insipid, and without action upon polarised light; it is decomposed by dilute acids into dextrose and levulose, has then a sweet taste, and is then directly fermentable; it is coloured black by concentrated sulphuric acid in the cold, but is not turned brown by caustic potassa at the ordinary temperature. Nitrate of silver produces, in the cold, a white flocculent precipitate; on heating, reduction takes place. Mercurous salts are reduced in the cold. The compounds with lime and baryta are soluble in water, but insoluble in alcohol. The formula of synanthrose is $\text{C}_{12}\text{H}_{22}\text{O}_{11}$; that of the baryta compound, $\text{C}_{12}\text{H}_{22}\text{O}_{11} \cdot \text{BaO}$. This substance (synanthrose) prevents the precipitation of cupric, ferric, and chromic oxides by alkalies; freshly-precipitated ferric oxide is dissolved by a solution of synanthrose.

Programm der Königlichen Rheinisch-Westphälischen Polytechnischen Schule zu Aachen, für den Coursus, 1871-72.

We owe to the politeness of the excellent director of this establishment the opportunity of once more calling attention to the Royal Rheinisch-Westphalian Polytechnic School founded at Charlemagne's ancient and favourite city of Aix-la-Chapelle (Aachen). The pro-

gramme before us, a volume of 112 large octavo pages, exclusive of two large-sized tabulated forms, is valuable also as an example of what polytechnic instruction really means. The course of instruction intended to be given at the Polytechnic School at Aachen, from the 9th of October next, is plainly described in this volume, to which a loose sheet is added containing well drawn up hints and good advice for those who desire to attend the instruction of a polytechnicum, as it is properly termed. The various subjects on which lectures and practical instruction are given embrace no less than sixty different branches, and include, not only all matters relating to mathematics, geometry, and physical sciences, but also everything required by the civil and mechanical engineer, architect, industrial and technical chemist, metallurgist, and mining engineer, including a subject for which there is no single equivalent word in English—"salinenkunde"—that is to say, all things relating to the extraction of salt from saline springs and the working of salt deposits; further, also, electrical telegraphy, practical instruction in the construction of chemical and metallurgical works; political economy, stenography, anatomy, and physiology; special "*gewerbe sanitäts polizei*"—that is to say, the manufacturing industry considered in its relation to, and bearing upon, the health and well-being, as well of the workmen, artisans, and labourers employed as of the rest of the population, and also treating on the requirements of public and other buildings in respect of ventilation, lighting, heating, &c. The Polytechnic School possesses excellent libraries, laboratories, workshops, museums, and collections of various kinds, to which donations of high value from various countries and private individuals (185 in number) have been added during the past year, a complete catalogue of which is published at the end of the programme. Science forbids us to enter here into more details, but we must not omit to state that, according to the *palmum qui meruit ferat*, everything has been and is being done to make this Polytechnic School a focus of attraction, not only for Germans, but for students from all parts of the world who are desirous of obtaining sound theoretical and practical instruction, as applied to arts, manufactures, mines, and engineering.

Journal für Gasbeleuchtung und Wasserversorgung, No. 12, 1871.

This number does not contain any other original papers than those strictly relating to the subjects of gas- and water-works' management and engineering. For those who may be interested in such matters, we call attention to a paper on the—

Yield and Consumption of Petroleum in America and other parts of the World.—Dr. Schilling.—This paper contains, in a condensed form, a valuable amount of statistical information on the subject alluded to.

NOTES AND QUERIES.

Anthracene.—Would you kindly inform me of a good method of separating anthracene for the heavy oil of tar, a method of purifying the same, and its uses?—HENRY DORSETT.

Cement to Resist Nitric Acid.—Will you kindly inform me what is the best cement to make the joints of a stone cistern to resist nitric acid?—T. KENYON, jun.

A New Form of Mariner's Compass.—I understand that, at a recent sitting of the French Academy of Sciences, a curious communication was received from M. Zalewski, which, if borne out in practice, would be invaluable to navigation. He states that if a hollow cylinder made of thin materials, open at the top, and provided with a sharp-edged bottom, be properly ballasted, and then put into a tub or other vessel filled with water, it will soon move in a never-varying direction from west to east! The round tin boxes in which concentrated milk is preserved will do perfectly for the experiment, which will become more and more perceptible the oftener the same cylinder is employed in the experiment. Can any of your readers give me additional information on this subject?—ALPHA.

TO CORRESPONDENTS.

* * Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxiv, commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

J. B.—Dr. R. Angus Smith, of All Saints, Manchester, is the principal inspector under the Alkali Act.

J. Reddop.—It should have been "carbon;" the meaning is, however, apparent.

Agri. Chem.—In the *Journal of the Chemical Society*.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum, payable in advance.

Royal 8vo., pp. 388, price 7s. 6d. Third Edition.

The Patentee's Manual; being a Treatise on the Law and Practice of Letters Patent, especially intended for the use of Patentees and Inventors. By JAMES JOHNSON, Barrister-at-Law; and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent.

The call for a Third Edition of this work is conclusive proof that it satisfies a want on the part of Patentees and Inventors, to whom a plain statement of the law bearing upon the subject of Letters Patent for Inventions is obviously a matter of great importance. Whilst the exposition of statutes and judicial decisions is expressed in plain and popular language, no sacrifice has been made of legal accuracy, and it will be found that the work contains a concise but ample and strictly correct enunciation of the law, with an examination of the decided cases to the latest date.

London: Longmans, Green, and Co.

Just published, price One shilling.

A Concise View of the Law connected with Letters Patent for Inventions. By JAMES JOHNSON, of the Middle Temple, Barrister-at-Law, and J. HENRY JOHNSON, Assoc. Inst. C.E., Solicitor and Patent Agent, Lincoln's Inn Fields and Glasgow. Authors of the "Patentee's Manual."

London: Longmans, Green and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—PARIS EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships' Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

OWEN'S COLLEGE, MANCHESTER,

The Session commences on the 2nd of October. Persons seeking Admission as Students must be not under fourteen years of age. Prospectuses of the Day or Evening Classes, and of the Scholarships and Entrance Exhibitions tenable at the College, will be sent on application.

J. HOLME NICHOLSON, Registrar.

St. Mary's Hospital Medical School.—Open SCHOLARSHIP AND EXHIBITION IN NATURAL SCIENCE.

A SCHOLARSHIP of the value of £40, tenable for three years, and an EXHIBITION of the value of £20, for one year, will be awarded by open competitive Examination in Natural Science, at St. Mary's Medical School, on September 26th and following days.

Any person will be eligible as a candidate who has passed an Examination qualifying him to register as a Medical Student, provided he has not previously completed a full year of medical study at a recognised Hospital.

Candidates are requested to call personally upon the Dean at the School, on Monday, Sept. 25th, between the hours of 3 and 5 p.m., and to bring with them a certificate of having passed the required preliminary Examination.

Further information as to the subjects of Examination, and the conditions under which the Scholarship and Exhibition will be held, may be obtained from Dr. Cheadle, the Dean, or from Mr. Knott, the Registrar, at the Hospital.

W. B. CHEADLE, M.D., Dean of the School.

Chloride of Calcium (Purified Muriate of Lime),

total insoluble impurities under ¼ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under ¼ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

STEATITE.

Above can be had in quantity, free on board or rail, Portsoy, Banffshire, N.B.—Apply to W. Ross Hutton and Co., Chemical Works, Burghhead.

ESTABLISHED 1798.

ROBERT DAGLISH & CO., BOILER MAKERS, ENGINEERS, AND MILL-WRIGHTS, BRASS AND IRONFOUNDERS, ST. HELEN'S FOUNDRY, LANCASHIRE.

Manufacturers of every description of Chemical Plant, as supplied to the largest Alkali Makers in England, Ireland, Scotland, and Wales. Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Vertical Blowing Engines (which have given a much higher Blast than any others have yet obtained), and as supplied to the entire satisfaction of some of the largest Bleaching Powder Manufacturers who have adopted "Weldon's Patent Process."

Plans and Estimates of the whole of this Plant supplied in accordance with the Patentee's instructions.

Photographs, Prices, and other information, given on receipt of Order.

OXIDE OF IRON.

We are prepared to supply, on moderate terms, HYDRATED PEROXIDE OF IRON (BOG OCHRE), Same quality as supplied by us to several of the most extensive Gas Companies, and which has given entire satisfaction.

FRANCIS RITCHIE AND SONS, BELFAST.

PARIS UNIVERSAL EXHIBITION, 1867.

THE SILVER PRIZE MEDAL

HAS BEEN AWARDED TO

LEWIS DEMUTH & CO.,

TAR DISTILLERS,

SPRINGFIELD CHEMICAL WORKS,
OLDBURY, NEAR BIRMINGHAM.

FOR THE

BEST CARBOLIC ACID AND BENZINE EXHIBITED.

CRUDE NAPHTHA AND LIGHT OIL PURCHASED.

W. NEILL & SON'S PATENT BLOWING ENGINES, ACID PUMPS, AND DONKEY PUMPS,

ESPECIALLY ADAPTED FOR

WELDON'S PATENT CHLORINE PROCESS.

W. NEILL and SON have just Patented most important improvements in the Air-Valves of Blowing-Engines, which enable them to secure the most perfect "Cut-off" at the termination of each stroke, together with a perfectly free inlet and outlet for the Air at the proper time, thus securing a much better result from each stroke of the Air-Piston, with greater freedom of action, also a very great saving in the wear and tear of valves.

These improvements are of especial advantage to Engines working under the comparatively high pressure of blast required in the Weldon Process.

W. Neill and Son have supplied Blowing Engines and Pumps to all the principal Alkali Makers who have adopted the Weldon Process, and are ready to furnish Plans and Estimates for the erection (with the latest improvements) of the whole of the Plant required.

Efficiency and Simplicity of Construction, with the best workmanship, guaranteed. References on application.

W. NEILL and SON, ENGINEERS, &c.,
BOLD, ST. HELEN'S JUNCTION, LANCASHIRE.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

THE CHEMICAL NEWS.

VOL. XXIV. No. 610.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

EDINBURGH MEETING, AUGUST 2, 1871.

INAUGURAL ADDRESS OF THE PRESIDENT,

SIR WILLIAM THOMSON, KNT., LL.D., F.R.S., &c.,
Professor of Natural Philosophy in the University of Glasgow.

MY LORDS, LADIES, AND GENTLEMEN,—

For the third time of its forty years' history the British Association is assembled in the metropolis of Scotland. The origin of the Association is connected with Edinburgh in undying memory through the honoured names of Robison, Brewster, Forbes, and Johnston.

In this place, from this chair, twenty-one years ago, Sir David Brewster said:—"On the return of the British Association to the metropolis of Scotland I am naturally reminded of the small band of pilgrims who carried the seeds of this Institution into the more genial soil of our sister land. . . . Sir John Robison, Professor Johnston, and Professor J. D. Forbes were the earliest friends and promoters of the British Association. They went to York to assist in its establishment, and they found there the very men who were qualified to foster and organise it. The Rev. Mr. Vernon Harcourt, whose name cannot be mentioned here without gratitude, had provided laws for its government, and, along with Mr. Phillips, the oldest and most valuable of our office-bearers, had made all those arrangements by which its success was ensured. Headed by Sir Roderick Murchison, one of the very earliest and most active advocates of the Association, there assembled at York about 200 of the friends of Science."

The statement I have read contains no allusion to the real origin of the British Association. This blank in my predecessor's historical sketch I am able to fill in from words written by himself twenty years earlier. Through the kindness of Professor Phillips, I am enabled to read to you part of a letter to him at York, written by David Brewster from Allerly by Melrose, on the 23rd of February, 1831:—

"Dear Sir,—I have taken the liberty of writing you on a subject of considerable importance. It is proposed to establish a British Association of men of science similar to that which has existed for eight years in Germany, and which is now patronised by the most powerful sovereigns of that part of Europe. The arrangements for the first meeting are in progress; and it is contemplated that it shall be held in York, as the most central city for the three kingdoms. My object in writing you at present is to beg that you would ascertain if York will furnish the accommodation necessary for so large a meeting (which may, perhaps, consist of above 100 individuals), if the Philosophical Society would enter zealously into the plan, and if the Mayor and influential persons in the town and in the vicinity would be likely to promote its objects. The principal object of the Society would be to make the cultivators of science acquainted with each other, to stimulate one another to new exertions, and to bring the objects of science more before the public eye, and to take measures for advancing its interests and accelerating its progress."

Of the little band of four pilgrims from Scotland to York not one now survives. Of the seven first Associates, one

more has gone over to the majority since the Association last met. Vernon Harcourt is no longer with us; but his influence remains, a beneficent, and surely, therefore, never dying, influence. He was a geologist and chemist, a large-hearted lover of science, and an unwearied worker for its advancement. Brewster was the founder of the British Association; Vernon Harcourt was its law-giver. His code remains to this day the law of the Association.

On the eleventh of May last, Sir John Herschel died in the eightieth year of his age. The name of Herschel is a household word throughout Great Britain and Ireland—yes, and through the whole civilised world. We of this generation have, from our lessons of childhood upwards, learned to see in Herschel, father and son, a *præsidium et dulces decus* of the precious treasure of British scientific fame. When geography, astronomy, and the use of the globes were still taught, even to poor children, as a pleasant and profitable sequel to "reading, writing, and arithmetic," which of us did not revere the great telescope of Sir William Herschel (one of the hundred wonders of the world), and learn with delight, directly or indirectly from the charming pages of Sir John Herschel's book, about the sun and his spots, and the fiery tornadoes sweeping over his surface, and about the planets, and Jupiter's belts, and Saturn's rings, and the fixed stars with their proper motions, and the double stars, and coloured stars, and the nebulae discovered by the great telescope? Of Sir John Herschel it may indeed be said, *nihil tetigit quod non ornavit*.

A monument to Faraday, and a monument to Herschel, Britain must have. The nation will not be satisfied with anything, however splendid, done by private subscription. A national monument, the more humble in point of expense the better, is required to satisfy that honourable pride with which a high-spirited nation cherishes the memory of its great men. But, for the glory of Faraday or the glory of Herschel, is a monument wanted? No!

What needs my Shakspeare for his honoured bones
The labour of an age in piled stones?
Or that his hallowed reliques should be hid
Under a star-ypointing pyramid?
Dear son of memory, great heir of fame,
What need'st thou such weak witness of thy name!
Thou, in our wonder and astonishment,
Hast built thyself a live-long monument.

And, so sepulchred, in such pomp dost lie,
That kings for such a tomb would wish to die.

With regard to Sir John Herschel's scientific work, on the present occasion I can but refer briefly to a few points which seem to me salient in his physical and mathematical writings. First, I remark that he has put forward, most instructively and profitably to his readers, the general theory of periodicity in dynamics, and has urged the practical utilising of it, especially in meteorology, by the harmonic analysis.

Sir John Herschel's discovery of a right or left-handed asymmetry in the outward form of crystals, such as quartz, which, in their inner molecular structure, possess the helicoidal rotational property in reference to the plane of polarisation of light, is one of the notable points of meeting between natural history and natural philosophy. His observations on "epipolic dispersion" gave Stokes the clue by which he was led to his great discovery of the change of periodic time experienced by light in falling on certain substances and being dispersively reflected from them. In respect to pure mathematics, Sir John Herschel did more, I believe, than any other man to introduce into Britain the powerful methods and the valuable notation of modern analysis. A remarkable mode of symbolism had freshly appeared, I believe, in the works of Laplace, and possibly of other French mathematicians; it certainly appeared in Fourier, but whether before or after Herschel's work I cannot say. Of Herschel's gigantic work in astronomical observation I need say nothing. Doubtless a careful account of it will be given in the *Proceedings of the Royal Society of London* for the next anniversary meeting.

In the past year, another representative man of British science is gone. Mathematics had no steadier supporter for half a century than De Morgan. His great book on the differential calculus was, for the mathematical student of thirty years ago, a highly-prized repository of all the best things that could be brought together under that title. I do not believe it is less valuable now; and if it is less valued, may this not be because it is too good for examination purposes, and because the modern student, labouring to win marks in the struggle for existence, must not suffer himself to be beguiled from the stern path of duty by any attractive beauties in the subject of his study?

One of the most valuable services to science which the British Association has performed has been the establishment, and the twenty-nine year's maintenance, of its Observatory. The magnificent services which it has rendered to science are so well known that any statement of them which I could attempt on the present occasion would be superfluous. Their value is due in a great measure to the indefatigable zeal and the great ability of two Scotchmen, both from Edinburgh, who successively held the office of Superintendent of the Observatory of the British Association—Mr. Welsh for nine years, until his death in 1859, and Dr. Balfour Stewart from then until the present time. Fruits of their labours are to be found all through our volumes of Reports for these twenty-one years.

The institution now enters on a new stage of its existence. The noble liberality of a private benefactor, one who has laboured for its welfare with self-sacrificing devotion unintermittingly from within a few years of its creation, has given it a permanent independence, under the general management of a Committee of the Royal Society. Mr. Gassiot's gift of £10,000 secures the continuance at Kew of the regular operation of the self-recording instruments for observing the phenomena of terrestrial magnetism and meteorology, without the necessity for further support from the British Association.

The success of the Kew Magnetic and Meteorological Observatory affords an example of the great gain to be earned for science by the foundation of physical observatories and laboratories for experimental research, to be conducted by qualified persons, whose duties should be, not teaching, but experimenting. Whether we look to the honour of England, as a nation which ought always to be the foremost in promoting physical science, or to those vast economical advantages which must accrue from such establishments, we cannot but feel that experimental research ought to be made with us an object of national concern, and not left, as hitherto, exclusively to the private enterprise of self-sacrificing amateurs, and the necessarily inconsecutive action of our present Governmental Departments and of casual Committees. The Council of the Royal Society of Edinburgh has moved for this object in a memorial presented by them to the Royal Commission on Scientific Education and the Advancement of Science.

The physical laboratories which have grown up in the Universities of Glasgow and Edinburgh, and in Owen's College, Manchester, show the want felt of Colleges of Research; but they go but infinitesimally towards supplying it, being absolutely destitute of means, material or personal, for advancing science except at the expense of volunteers, or securing that volunteers shall be found to continue even such little work as at present is carried on.

The whole of Andrews's splendid work in Queen's College, Belfast, has been done under great difficulties and disadvantages, and at great personal sacrifices; and up to the present time there is not a student's physical laboratory in any one of the Queen's Colleges in Ireland—a want which surely ought not to remain unsupplied. Each of these institutions (the four Scotch Universities, the three Queen's Colleges, and Owen's College, Manchester) requires two professors of Natural Philosophy—one who shall be responsible for the teaching, the other for the advancement of science by experiment. The University

of Oxford has already established a physical laboratory. The munificence of its Chancellor is about to supply the University of Cambridge with a splendid laboratory, to be constructed under the eye of Professor Clerk Maxwell. On this subject I shall say no more at present, but simply read a sentence which was spoken by Lord Milton in the first Presidential Address to the British Association, when it met at York in the year 1831:—"In addition to more direct benefits, these meetings [of the British Association], I hope, will be the means of impressing on the Government the conviction that the love of scientific pursuits, and the means of pursuing them, are not confined to the metropolis; and I hope that when the Government is fully impressed with the knowledge of the great desire entertained to promote science in every part of the empire, they will see the necessity of affording it due encouragement, and of giving every proper stimulus to its advancement."

Besides abstracts of papers read, and discussions held, before the Sections, the Annual Reports of the British Association contain a large mass of valuable matter of another class. It was an early practice of the Association, a practice that might well be further developed, to call occasionally for a special report on some particular branch of science from a man eminently qualified for the task. The reports received in compliance with these invitations have all done good service in their time, and they remain permanently useful as landmarks in the history of science. Some of them have led to vast practical results; others of a more abstract character are valuable to this day as powerful and instructive condensations and expositions of the branches of science to which they relate. I cannot better illustrate the two kinds of efficiency realised in this department of the Association's work than by referring to Cayley's Report on Abstract Dynamics* and Sabine's Report on Terrestrial Magnetism† (1838).

In referring to recent advances in several branches of science, I simply choose some of those which have struck me as most notable.

Accurate and minute measurement seems to the non-scientific imagination a less lofty and dignified work than looking for something new. But nearly all the grandest discoveries of science have been but the rewards of accurate measurement and patient long-continued labour in the minute sifting of numerical results. The popular idea of Newton's grandest discovery is that the theory of gravitation flashed into his mind, and so the discovery was made. It was by a long train of mathematical calculation, founded on results accumulated through prodigious toil of practical astronomers, that Newton first demonstrated the forces urging the planets towards the sun, determined the magnitudes of those forces, and discovered that a force following the same law of variation with distance urges the moon towards the earth. Then first, we may suppose, came to him the idea of the universality of gravitation; but when he attempted to compare the magnitude of the force on the moon with the magnitude of the force of gravitation of a heavy body of equal mass at the earth's surface, he did not find the agreement which the law he was discovering required. Not for years after would he publish his discovery as made. It is recounted that, being present at a meeting of the Royal Society, he heard a paper read, describing geodesic measurement by Picard, which led to a serious correction of the previously accepted estimate of the earth's radius. This was what Newton required. He went home with the result, and commenced his calculations, but felt so much agitated that he handed over the arithmetical work to a friend; then (and not when sitting in a garden he saw an apple fall) did he ascertain that gravitation keeps the moon in her orbit.

Faraday's discovery of specific inductive capacity, which inaugurated the new philosophy tending to discard action

* Report on the Recent Progress of Theoretical Dynamics, by A. Cayley (Report of the British Association 1857, p. 1).

† Report on the Variations of the Magnetic Intensity observed at different points of the Earth's Surface, by Major Sabine, F.R.S. (forming part of the 7th Report of the British Association).

at a distance, was the result of minute and accurate measurement of electric forces.

Joule's discovery of thermo-dynamic law through the regions of electro-chemistry, electro-magnetism, and elasticity of gases was based on a delicacy of thermometry which seemed simply impossible to some of the most distinguished chemists of the day.

Andrew's discovery of the continuity between the gaseous and liquid states was worked out by many years of laborious and minute measurement of phenomena scarcely sensible to the naked eye.

Great service has been done to science by the British Association in promoting accurate measurement in various subjects. The origin of exact science in terrestrial magnetism is traceable to Gauss's invention, of methods of finding the magnetic intensity in absolute measure. I have spoken of the great work done by the British Association in carrying out the application of this invention in all parts of the world. Gauss's colleague in the German Magnetic Union, Weber, extended the practice of absolute measurement to electric currents, the resistance of an electric conductor, and the electromotive force of a galvanic element. He showed the relation between electrostatic and electro-magnetic units for absolute measurement, and made the beautiful discovery that resistance, in absolute electro-magnetic measure, and the reciprocal of resistance, or, as we call it, "conducting power," in electrostatic measure, are each of them a velocity. He made an elaborate and difficult series of experiments to measure the velocity which is equal to the conducting power, in electrostatic measure, and at the same time to the resistance in electro-magnetic measure, in one and the same conductor. Maxwell, in making the first advance along a road of which Faraday was the pioneer, discovered that this velocity is physically related to the velocity of light, and that, on a certain hypothesis regarding the elastic medium concerned, it may be exactly equal to the velocity of light. Weber's measurement verifies approximately this equality, and stands in science *monumentum ære perennius*, celebrated as having suggested this most grand theory, and as having afforded the first quantitative test of the recondite properties of matter on which the relations between electricity and light depend. A re-measurement of Weber's critical velocity on a new plan by Maxwell himself, and the important correction of the velocity of light by Foucault's laboratory experiments, verified by astronomical observation, seem to show a still closer agreement. The most accurate possible determination of Weber's critical velocity is just now a primary object of the Association's Committee on Electric Measurement; and it is at present premature to speculate as to the closeness of the agreement between that velocity and the velocity of light. This leads me to remark how much science, even in its most lofty speculations, gains in return for benefits conferred by its application to promote the social and material welfare of man. Those who perilled and lost their money in the original Atlantic Telegraph were impelled and supported by a sense of the grandeur of their enterprise, and of the world-wide benefits which must flow from its success; they were at the same time not unmoved by the beauty of the scientific problem directly presented to them; but they little thought that it was to be immediately, through their work, that the scientific world was to be instructed in a long-neglected and discredited fundamental electric discovery of Faraday's, or that, again, when the assistance of the British Association was invoked to supply their electricians with methods for absolute measurement (which they found necessary to secure the best economical return for their expenditure, and to obviate and detect those faults in their electric material which had led to disaster), they were laying the foundation for accurate electric measurement in every scientific laboratory in the world, and initiating a train of investigation which now sends up branches into the loftiest regions and subtlest ether of natural philosophy. Long may the British Association continue a bond of

union, and a medium for the interchange of good offices between science and the world!

The greatest achievement yet made in molecular theory of the properties of matter is the Kinetic theory of Gases, shadowed forth by Lucretius, definitely stated by Daniel Bernoulli, largely developed by Herapath, made a reality by Joule, and worked out to its present advanced state by Clausius and Maxwell. Joule, from his dynamical equivalent of heat, and his experiments upon the heat produced by the condensation of gas, was able to estimate the average velocity of the ultimate molecules or atoms composing it. His estimate for hydrogen was 6225 feet per second at temperature 60° F., and 6055 feet per second at the freezing-point. Clausius took fully into account the impacts of molecules on one another, and the kinetic energy of relative motions of the matter constituting an individual atom. He investigated the relation between their diameters, the number in a given space, and the mean length of path from impact to impact, and so gave the foundation for estimates of the absolute dimensions of atoms, to which I shall refer later. He explained the slowness of gaseous diffusion by the mutual impacts of the atoms, and laid a secure foundation for a complete theory of the diffusion of fluids, previously a most refractory enigma. The deeply penetrating genius of Maxwell brought in viscosity and thermal conductivity, and thus completed the dynamical explanation of all the known properties of gases, except their electric resistance and brittleness to electric force.

When the theory, of which we have the first instalment in Clausius and Maxwell's work, is complete, we are but brought face to face with a superlatively grand question, What is the inner mechanism of the atom?

In the answer to this question we must find the explanation not only of the atomic elasticity, by which the atom is a chronometric vibrator according to Stokes's discovery, but of chemical affinity and of the differences of quality of different chemical elements, at present a mere mystery in science. Helmholtz's exquisite theory of vortex-motion in an incompressible frictionless liquid has been suggested as a finger-post, pointing a way which may possibly lead to a full understanding of the properties of atoms, carrying out the grand conception of Lucretius, who "admits no subtle ethers, no variety of elements with fiery, or watery, or light, or heavy principles; nor supposes light to be one thing, fire another, electricity a fluid, magnetism a vital principle, but treats all phenomena as mere properties or accidents of simple matter." This statement I take from an admirable paper on the atomic theory of Lucretius, which appeared in the *North British Review* for March, 1868, containing a most interesting and instructive summary of ancient and modern doctrine regarding atoms. Allow me to read from that article one other short passage finely describing the present aspect of atomic theory:—"The existence of the chemical atom, already quite a complex little world, seems very probable; and the description of the Lucretian atom is wonderfully applicable to it. We are not wholly without hope that the real weight of each such atom may some day be known—not merely the relative weight of the several atoms, but the number in a given volume of any material; that the form and motion of the parts of each atom and the distances by which they are separated may be calculated; that the motions by which they produce heat, electricity, and light may be illustrated by exact geometrical diagrams; and that the fundamental properties of the intermediate and possibly constituent medium may be arrived at. Then the motion of planets and music of the spheres will be neglected for a while in admiration of the maze in which the tiny atoms run."

Even before this was written some of the anticipated results had been partially attained. Loschmidt in Vienna had shown, and not much later Stoney independently in England showed, how to deduce from Clausius and Maxwell's kinetic theory of gases a superior limit to the number of atoms in a given measurable space. I was unfor-

tunately quite unaware of what Loschmidt and Stoney had done when I made a similar estimate on the same foundation, and communicated it to *Nature* in an article on "The Size of Atoms." But questions of personal priority, however interesting they may be to the persons concerned, sink into insignificance in the prospect of any gain of deeper insight into the secrets of nature. The triple coincidence of independent reasoning in this case is valuable as confirmation of a conclusion violently contravening ideas and opinions which had been almost universally held regarding the dimensions of the molecular structure of matter. Chemists and other naturalists had been in the habit of evading questions as to the hardness or indivisibility of atoms by virtually assuming them to be infinitely small and infinitely numerous. We must now no longer look upon the atom, with Boscovich, as a mystic point endowed with inertia and the attribute of attracting or repelling other such centres with forces depending upon the intervening distances (a supposition only tolerated with the tacit assumption that the inertia and attraction of each atom is infinitely small and the number of atoms infinitely great), nor can we agree with those who have attributed to the atom occupation of space with infinite hardness and strength (incredible in any finite body); but we must realise it as a piece of matter of measurable dimensions, with shape, motion, and laws of action, intelligible subjects of scientific investigation.

The prismatic analysis of light discovered by Newton was estimated by himself as being "the oddest, if not the most considerable, detection which 'hath hitherto been made in the operations of nature.'"

Had he not been deflected from the subject, he could not have failed to obtain a pure spectrum; but this, with the inevitably consequent discovery of the dark lines, was reserved for the nineteenth century. Our fundamental knowledge of the dark lines is due solely to Fraunhofer. Wollaston saw them, but did not discover them. Brewster laboured long and well to perfect the prismatic analysis of sunlight; and his observations on the dark bands produced by the absorption of interposed gases and vapours laid important foundations for the grand superstructure which he scarcely lived to see. Piazzi Smyth, by spectroscopic observation performed on the Peak of Teneriffe, added greatly to our knowledge of the dark lines produced in the solar spectrum by the absorption of our own atmosphere. The prism became an instrument for chemical qualitative analysis in the hands of Fox Talbot and Herschel, who first showed how, through it, the old "blowpipe test" or generally the estimation of substances from the colours which they give to flames, can be prosecuted with an accuracy and a discriminating power not to be attained when the colour is judged by the unaided eye. But the application of this test to solar and stellar chemistry had never, I believe, been suggested, either directly or indirectly, by any other naturalist, when Stokes taught it to me in Cambridge at some time prior to the summer of 1852. The observational and experimental foundations on which he built were:—

(1). The discovery by Fraunhofer of a coincidence between his double dark line D, of the solar spectrum and a double bright line which he observed in the spectra of ordinary artificial flames.

(2). A very rigorous experimental test of this coincidence by Professor W. H. Miller, which showed it to be accurate to an astonishing degree of minuteness.

(3). The fact that the yellow light given out when salt is thrown on burning spirit consists almost solely of the two nearly identical qualities which constitute that double bright line.

(4). Observations made by Stokes himself, which showed the bright line, D, to be absent in a candle-flame when the wick was snuffed clean, so as not to project into the luminous envelope, and from an alcohol flame when the spirit was burned in a watch-glass. And

(5). Foucault's admirable discovery (*L'Institut*, Feb. 7, 1849) that the voltaic arc between charcoal points is "a

medium which emits the rays D on its own account, and at the same time absorbs them when they come from another quarter."

The conclusions, theoretical and practical, which Stokes taught me, and which I gave regularly afterwards in my public lectures in the University of Glasgow, were:—

(1). That the double line D, whether bright or dark, is due to vapour of sodium.

(2). That the ultimate atom of sodium is susceptible of regular elastic vibrations, like those of a tuning-fork or of stringed musical instruments; that like an instrument with two strings tuned to approximate unison, or an approximately circular elastic disk, it has two fundamental notes or vibrations of approximately equal pitch; and that the periods of these vibrations are precisely the periods of the two slightly different yellow lights constituting the double bright line D.

(3). That when vapour of sodium is at a high enough temperature to become itself a source of light, each atom executes these two fundamental vibrations simultaneously; and that, therefore, the light proceeding from it is of the two qualities constituting the double bright line D.

(4). That when vapour of sodium is present in space across which light from another source is propagated, its atoms, according to a well-known general principle of dynamics, are set to vibrate in either or both of those fundamental modes, if some of the incident light is of one or other of their periods, or some of one and some of the other; so that the energy of the waves of those particular qualities of light is converted into thermal vibrations of the medium and dispersed in all directions, while light of all other qualities, even though very nearly agreeing with them, is transmitted with comparatively no loss.

(5). That Fraunhofer's double dark line D of solar and stellar spectra is due to the presence of vapour of sodium in atmospheres surrounding the sun and those stars in whose spectra it had been observed.

(6). That other vapours than sodium are to be found in the atmospheres of sun and stars by searching for substances producing in the spectra of artificial flames bright lines coinciding with other dark lines of the solar and stellar spectra than the Fraunhofer line D.

The last of these propositions I felt to be confirmed (it was, perhaps, partly suggested) by a striking and beautiful experiment admirably adapted for lecture illustrations, due to Foucault, which had been shown to me by M. Duboscque Soleil, and the Abbé Moigno, in Paris in the month of October, 1850. A prism and lenses were arranged to throw upon a screen an approximately pure spectrum of a vertical electric arc between charcoal poles of a powerful battery, the lower one of which was hollowed like a cup. When pieces of copper and pieces of zinc were separately thrown into the cup, the spectrum exhibited, in perfectly definite positions, magnificent well-marked bands of different colours characteristic of the two metals. When a piece of brass, compounded of copper and zinc, was put into the cup, the spectrum showed all the bands, each precisely in the place in which it had been seen when one metal or the other had been used separately.

It is much to be regretted that this great generalisation was not published to the world twenty years ago. I say this, not because it is to be regretted that Ångström should have the credit of having in 1853 published independently the statement that "an incandescent gas emits 'luminous rays of the same refrangibility as those which it can absorb;'" or that Balfour Stewart should have been unassisted by it when, coming to the subject from a very different point of view, he made, in his extension of the "Theory of Exchanges,"* the still wider generalisation that the radiating power of every kind of substance is equal to its absorbing power for every kind of ray; or that Kirchhoff also should have in 1859 independently discovered the same proposition, and shown its application to solar and stellar chemistry; but because we might now

* *Edin. Transactions*, 1858-59.

be in possession of the inconceivable riches of astronomical results which we expect from the next ten years' investigation by spectrum analysis, had Stokes given his theory to the world when it first occurred to him.

To Kirchhoff belongs, I believe, solely the great credit of having first actually sought for and found other metals than sodium in the sun by the method of spectrum analysis. His publication of October, 1859, inaugurated the practice of solar and stellar chemistry, and gave spectrum analysis an impulse to which, in a great measure, is due its splendidly successful cultivation by the labours of many able investigators within the last ten years.

Plücker and Hittorf opened ground in advancing the physics of spectrum analysis and made the important discovery of changes in the spectra of ignited gases produced by changes in the physical condition of the gas. The scientific value of the meetings of the British Association is well illustrated by the fact that it was through conversation with Plücker at the Newcastle meeting that Lockyer was first led into the investigation of the effects of varied pressure on the quality of the light emitted by glowing gas which he and Frankland have prosecuted with such admirable success. Scientific wealth tends to accumulation according to the law of compound interest. Every addition to knowledge of properties of matter supplies the naturalist with new instrumental means for discovering and interpreting phenomena of nature, which, in their turn, afford foundations for fresh generalisations, bringing gains of permanent value into the great stock-house of philosophy. Thus Frankland, led, from observing the want of brightness of a candle burning in a tent on the summit of Mont Blanc, to scrutinise Davy's theory of flame, discovered that brightness without incandescent solid particles is given to a purely gaseous flame by augmented pressure, and that a dense ignited gas gives a spectrum comparable with that of the light from an incandescent solid or liquid. Lockyer joined him; and the two found that every incandescent substance gives a continuous spectrum—that an incandescent gas under varied pressure gives bright bars across the continuous spectrum, some of which, from the sharp, hard, and fast lines observed where the gas is in a state of extreme attenuation, broaden out on each side into nebulous bands as the density is increased, and are ultimately lost in the continuous spectrum when the condensation is pushed on till the gas becomes a fluid no longer to be called gaseous. More recently they have examined the influence of temperature, and have obtained results which seem to show that a highly attenuated gas, which at a high temperature gives several bright lines, gives a smaller and smaller number of lines, of sufficient brightness to be visible, when the temperature is lowered, the density being kept unchanged. I cannot refrain here from remarking how admirably this beautiful investigation harmonises with Andrews's great discovery of continuity between the gaseous and liquid states. Such things make the life-blood of science. In contemplating them we feel as if led out from narrow waters of scholastic dogma to a refreshing excursion on the broad and deep ocean of truth, where we learn from the wonders we see that there are endlessly more and more glorious wonders still unseen.

Stokes's dynamical theory supplies the key to the philosophy of Frankland and Lockyer's discovery. Any atom of gas, when struck and left to itself, vibrates with perfect purity its fundamental note or notes. In a highly attenuated gas each atom is very rarely in collision with other atoms, and therefore is nearly at all times in a state of true vibration. Hence the spectrum of a highly attenuated gas consists of one or more perfectly sharp bright lines, with a scarcely perceptible continuous gradation of prismatic colour. In denser gas, each atom is frequently in collision, but still is for much more time free, in intervals between collisions, than engaged in collision; so that not only is the atom itself thrown sensibly out of tune during a sensible proportion of its whole time, but the confused jangle of vibrations in every variety of

period during the actual collision becomes more considerable in its influence. Hence, bright lines in the spectrum broaden out somewhat, and the continuous spectrum becomes less faint. In still denser gas, each atom may be almost as much time in collision as free, and the spectrum then consists of broad nebulous bands crossing a continuous spectrum of considerable brightness. When the medium is so dense that each atom is always in collision, that is to say, never free from influence of its neighbours, the spectrum will generally be continuous, and may present little or no appearance of bands, or even of maxima of brightness. In this condition the fluid can be no longer regarded as a gas, and we must judge of its relation to the vaporous or liquid states according to the critical conditions discovered by Andrews.

While these great investigations of properties of matter were going on, naturalists were not idle with the newly-recognised power of the spectroscopic at their service. Chemists soon followed the example of Bunsen, in discovering new metals in terrestrial matter by the old blow-pipe and prism test of Fox Talbot and Herschel. Biologists applied spectrum analysis to animal and vegetable chemistry, and to sanitary investigations. But it is in astronomy that spectroscopic research has been carried on with the greatest activity, and been most richly rewarded with results. The chemist and the astronomer have joined their forces. An astronomical observatory has now appended to it a stock of reagents such as hitherto was only to be found in the chemical laboratory. A devoted corps of volunteers of all nations, whose motto might well be *ubique*, have directed their artillery to every region of the universe. The sun, the spots on his surface, the corona, and the red and yellow prominences seen round him during total eclipses, the moon, the planets, comets, auroras, nebulae, white stars, yellow stars, red stars, variable and temporary stars, each tested by the prism, was compelled to show its distinguishing prismatic colours. Rarely before in the history of science has enthusiastic perseverance, directed by penetrative genius, produced within ten years so brilliant a succession of discoveries. It is not merely the *chemistry* of sun and stars, as first suggested, that is subjected to analysis by the spectroscope. Their whole laws of being are now subjects of direct investigation; and already we have glimpses of their evolutionary history through the stupendous power of this most subtle and delicate test. We had only solar and stellar chemistry; we now have solar and stellar physiology.

It is an old idea that the colour of a star may be influenced by its motion relatively to the eye of the spectator, so as to be tinged with red if it moves from the earth, or blue if it moves towards the earth. William Allen Miller, Huggins, and Maxwell showed how, by aid of the spectroscope, this idea may be made the foundation of a method of measuring the relative velocity with which a star approaches to, or recedes from, the earth. The principle is, first to identify, if possible, one or more of the lines in the spectrum of the star, with a line or lines in the spectrum of sodium, or some other terrestrial substance, and then (by observing the star and the artificial light simultaneously by the same spectroscope) to find the difference, if any, between their refrangibilities. From this difference of refrangibility the ratio of the periods of the two lights is calculated, according to data determined by Fraunhofer from comparisons between the positions of the dark lines in the prismatic spectrum and in his own "interference spectrum" (produced by substituting for the prism a fine grating). A first comparatively rough application of the test by Miller and Huggins to a large number of the principal stars of our skies, including Aldebaran, α Orionis, β Pegasi, Sirius, α Lyrae, Capella, Arcturus, Pollux, Castor (which they had observed rather for the chemical purpose than for this), proved that not one of them had so great a velocity as 315 kilometres per second to or from the earth, which is a *most momentous result in respect to cosmical dynamics*. Afterwards, Huggins made

special observations of the velocity test, and succeeded in making the measurement in one case, that of Sirius, which he then found to be receding from the earth at the rate of 66 kilometres per second. This, corrected for the velocity of the earth at the time of the observation, gave a velocity of Sirius, relatively to the sun, amounting to 47 kilometres per second. The minuteness of the difference to be measured, and the smallness of the amount of light, even when the brightest star is observed, renders the observation extremely difficult. Still, with such great skill as Mr. Huggins has brought to bear on the investigation, it can scarcely be doubted that velocities of many other stars may be measured. What is now wanted is, certainly not greater skill, perhaps not even more powerful instruments, but *more instruments and more observers*. Lockyer's applications of the velocity test to the relative motions of different gases in the sun's photosphere, spots, chromosphere, and chromospheric prominences, and his observations of the varying spectra presented by the same substance as it moves from one position to another in the sun's atmosphere, and his interpretations of these observations, according to the laboratory results of Frankland and himself, go far towards confirming the conviction that in a few years all the marvels of the sun will be dynamically explained according to known properties of matter.

During six or eight precious minutes of time, spectroscopes have been applied to the solar atmosphere and to the corona seen round the dark disc of the moon eclipsing the sun. Some of the wonderful results of such observations, made in India on the occasion of the eclipse of August, 1868, were described by Professor Stokes in a previous address. Valuable results have, through the liberal assistance given by the British and American Governments, been obtained also from the total eclipse of last December, notwithstanding a generally unfavourable condition of weather. It seems to have been proved that at least some sensible part of the light of the "corona" is a terrestrial atmospheric halo or dispersive reflection of the light of the glowing hydrogen and "helium" * round the sun. I believe I may say, on the present occasion, when preparation must again be made to utilise a total eclipse of the sun, that the British Association confidently trusts to our Government exercising the same wise liberality as heretofore in the interests of science.

For a few years Mayer's theory of solar heat had seemed to me probable; but I had been led to regard it as no longer tenable, because I had been in the first place driven, by consideration of the very approximate constancy of the earth's period of revolution round the sun for the last 2000 years, to conclude that "The principal source, perhaps the sole appreciably effective source, of sun-heat, is in bodies circulating round the sun at present inside the earth's orbit;"† and because Le Verrier's researches on the motion of the planet Mercury, though giving evidence of a sensible influence attributable to matter circulating as a great number of small planets within his orbit round the sun, showed that the amount of matter that could possibly be assumed to circulate at any considerable distance from the sun must be very small; and therefore "if the meteoric influx taking place at present is enough to produce any appreciable portion of the heat radiated away, it must be supposed to be from matter circulating round the sun, within very short distances of his surface. The density of this meteoric cloud would have to be supposed so great that comets could scarcely have escaped as comets actually have escaped, showing no discoverable effects of resistance, after passing his surface within a distance equal to one-eighth of his radius. All things considered, there seems little probability in the hypothesis that solar radiation is com-

pensated to any appreciable degree, by heat generated by meteors falling in, at present; and, as it can be shown that no chemical theory is tenable,* it must be concluded as most probable that the sun is at present merely an incandescent liquid mass cooling."†

Thus, on purely astronomical grounds, was I long ago led to abandon as very improbable the hypothesis that the sun's heat is supplied dynamically from year to year by the influx of meteors. But now spectrum analysis gives proof finally conclusive against it.

Each meteor circulating round the sun must fall in along a very gradual spiral path, and before reaching the sun must have been for a long time exposed to an enormous heating effect from his radiation when very near, and must thus have been driven into vapour before actually falling into the sun. Thus, if Mayer's hypothesis is correct, friction between vortices of meteoric vapours and the sun's atmosphere must be the immediate cause of solar heat; and the velocity with which these vapours circulate round equatorial parts of the sun must amount to 435 kilometres per second. The spectrum test of velocity applied by Lockyer showed but a twentieth part of this amount as the greatest observed relative velocity between different vapours in the sun's atmosphere.

At the first Liverpool meeting of the British Association (1854), in advancing a gravitational theory to account for all the heat, light, and motions of the universe, I urged that the immediately antecedent condition of the matter of which the sun and planets were formed, not being fiery, could not have been gaseous; but that it probably was solid, and may have been like the meteoric stones which we still so frequently meet with through space. The discovery of Huggins, that the light of the nebula, so far as hitherto sensible to us, proceeds from incandescent hydrogen and nitrogen gases, and that the heads of comets also give us light of incandescent gas, seems at first sight literally to fulfil that part of the Nebular hypothesis to which I had objected. But a solution, which seems to me in the highest degree probable, has been suggested by Tait. He supposes that it may be by ignited gaseous exhalations proceeding from the collision of meteoric stones that nebulae and the heads of comets show themselves to us, and he suggested, at a former meeting of the Association, that experiments should be made for the purpose of applying spectrum analysis to the light which has been observed in gunnery trials, such as those at Shoeburyness, when iron strikes against iron at a great velocity, but varied by substituting for the iron various solid materials, metallic or stony. Hitherto this suggestion has not been acted upon; but surely it is one the carrying out of which ought to be promoted by the British Association.

Most important steps have been recently made towards the discovery of the nature of comets; establishing with nothing short of certainty the truth of a hypothesis which had long appeared to me probable—that they consist of groups of meteoric stones;—accounting satisfactorily for the light of the nucleus; and giving a simple and rational explanation of phenomena presented by the tails of comets which had been regarded by the greatest astronomers as almost preternaturally marvellous. The meteoric hypothesis to which I have referred remained a mere hypothesis (I do not know that it was even ever published), until, in 1866, Schiaparelli calculated, from observations on the August meteors, an orbit for these bodies which he found to agree almost perfectly with the orbit of the great comet of 1862 as calculated by Oppolzer; and so discovered and demonstrated that a comet consists of a group of meteoric stones. Professor Newton, of Yale College, United States, by examining ancient records, ascertained that in periods of about thirty-three years, since the year 902, there have been exceptionally brilliant displays of the November meteors. It had long been believed that these interesting visitants came from a train

* Frankland and Lockyer find the yellow prominences to give a very decided bright line not far from D, but hitherto not identified with any terrestrial flame. It seems to indicate a new substance, which they propose to call Helium.

of small detached planets circulating round the sun all in nearly the same orbit, and constituting a belt analogous to Saturn's ring, and that the reason for the comparatively large number of meteors which we observe annually about the 14th of November is, that at that time the earth's orbit cuts through the supposed meteoric belt. Professor Newton concluded from his investigation that there is a denser part of the group of meteors which extends over a portion of the orbit so great as to occupy about one-tenth or one-fifteenth of the periodic time in passing any particular point, and gave a choice of five different periods for the revolution of this meteoric stream round the sun, any one of which would satisfy his statistical result. He further concluded that the line of nodes, that is to say, the line in which the plane of the meteoric belt cuts the plane of the earth's orbit, has a progressive sidereal motion of about 52.4" per annum. Here, then, was a splendid problem for the physical astronomer; and, happily, one well qualified for the task took it up. Adams, by the application of a beautiful method invented by Gauss, found that of the five periods allowed by Newton just one permitted the motion of the line of nodes to be explained by the disturbing influence of Jupiter, Saturn, and other planets. The period chosen on these grounds is 33½ years. The investigation showed further that the form of the orbit is a long ellipse, giving for shortest distance from the sun 145 million kilometres, and for longest distance 2895 million kilometres. Adams also worked out the longitude of the perihelion and the inclination of the orbit's plane to the plane of the ecliptic. The orbit which he thus found agreed so closely with that of Temple's Comet I. 1866 that he was able to identify the comet and the meteoric belt. The same conclusion had been pointed out a few weeks earlier by Schiaparelli, from calculations by himself on data supplied by direct observations on the meteors, and independently by Peters from calculations by Le Verrier on the same foundation. It is therefore thoroughly established that Temple's Comet I. 1866 consists of an elliptic train of minute planets, of which a few thousands or millions fall to the earth annually about the 14th of November, when we cross their track. We have probably not yet passed through the very nucleus or densest part; but thirteen times, in Octobers and Novembers, from October 13, A.D. 902 to November 14, 1866, inclusive (this last time having been correctly predicted by Prof. Newton), we have passed through a part of the belt greatly denser than the average. The densest part of the train, when near enough to us, is visible as the head of the comet. This astounding result, taken along with Huggins's spectroscopic observations on the light of the heads and tails of comets, confirm most strikingly Tait's theory of comets, to which I have already referred; according to which the comet, a group of meteoric stones, is self-luminous in its nucleus, on account of collisions among its constituents, while its "tail" is merely a portion of the less dense part of the train illuminated by sunlight, and visible or invisible to us according to circumstances, not only of density, degree of illumination, and nearness, but also of tactic arrangement, as of a flock of birds or the edge of a cloud of tobacco smoke!

The essence of science, as is well illustrated by astronomy and cosmical physics, consists in inferring antecedent conditions, and anticipating future evolutions, from phenomena which have actually come under observation. In biology the difficulties of successfully acting up to this ideal are prodigious. The earnest naturalists of the present day are, however, not appalled or paralysed by them, and are struggling boldly and laboriously to pass out of the mere "Natural History stage" of their study, and bring zoology within the range of Natural Philosophy. A very ancient speculation, still clung to by many naturalists (so much so that I have a choice of modern terms to quote in expressing it), supposes that, under meteorological conditions very different from the present, dead matter may have run together or crystallised or fermented

into "germs of life," or "organic cells," or "protoplasm." But science brings a vast mass of inductive evidence against this hypothesis of spontaneous generation, as you have heard from my predecessor in the Presidential chair. Careful enough scrutiny has, in every case up to the present day, discovered life as antecedent to life. Dead matter cannot become living without coming under the influence of matter previously alive. This seems to me as sure a teaching of science as the law of gravitation. I utterly repudiate, as opposed to all philosophical uniformitarianism, the assumption of "different meteorological conditions"—that is to say, somewhat different vicissitudes of temperature, pressure, moisture, gaseous atmosphere—to produce or to permit that to take place by force, or motion of dead matter alone, which is a direct contravention of what seems to us biological law. I am prepared for the answer, "Our code of biological law is an expression of our ignorance as well as of our knowledge." And I say "Yes; search for spontaneous generation out of inorganic materials; let any one not satisfied with the purely negative testimony of which we have now so much against it, throw himself into the inquiry." Such investigations as those of Pasteur, Pouchet, and Bastian are among the most interesting and momentous in the whole range of Natural History, and their results, whether positive or negative, must richly reward the most careful and laborious experimenting. I confess to being deeply impressed by the evidence put before us by Professor Huxley, and I am ready to adopt, as an article of scientific faith, true through all space and through all time, that life proceeds from life, and from nothing but life.

How, then, did life originate on the earth? Tracing the physical history of the earth backwards, on strict dynamical principles, we are brought to a red-hot melted globe on which no life could exist. Hence when the earth was first fit for life, there was no living thing on it. There were rocks solid and disintegrated, water, air all round, warmed and illuminated by a brilliant sun, ready to become a garden. Did grass and trees and flowers spring into existence, in all the fulness of ripe beauty, by a fiat of creative power? or did vegetation, growing up from seed sown, spread and multiply over the whole earth? Science is bound, by the everlasting law of honour, to face fearlessly every problem which can fairly be presented to it. If a probable solution, consistent with the ordinary course of nature, can be found, we must not invoke an abnormal act of creative power. When a lava stream flows down the sides of Vesuvius or Etna it quickly cools and becomes solid; and after a few weeks or years it teems with vegetable and animal life, which for it originated by the transport of seed and ova and by the migration of individual living creatures. When a volcanic island springs up from the sea, and after a few years is found clothed with vegetation, we do not hesitate to assume that seed has been wafted to it through the air, or floated to it on rafts. Is it not possible, and if possible, is it not probable, that the beginning of vegetable life on the earth is to be similarly explained? Every year thousands, probably millions, of fragments of solid matter fall upon the earth—whence came these fragments? What is the previous history of any one of them? Was it created in the beginning of time an amorphous mass? This idea is so unacceptable that, tacitly or explicitly, all men discard it. It is often assumed that all, and it is certain that some, meteoric stones are fragments which had been broken off from greater masses and launched free into space. It is as sure that collisions must occur between great masses moving through space as it is that ships, steered without intelligence directed to prevent collision, could not cross and re-cross the Atlantic for thousands of years with immunity from collisions. When two great masses come into collision in space it is certain that a large part of each is melted; but it seems also quite certain that in many cases a large quantity of debris must be shot forth in all directions, much of which may have

experienced no greater violence than individual pieces of rock experience in a land-slip or in blasting by gunpowder. Should the time when this earth comes into collision with another body, comparable in dimensions to itself, be when it is still clothed as at present with vegetation, many great and small fragments carrying seed and living plants and animals would undoubtedly be scattered through space. Hence and because we all confidently believe that there are at present, and have been from time immemorial, many worlds of life besides our own, we must regard it as probable in the highest degree that there are countless seed-bearing meteoric stones moving about through space. If at the present instant no life existed upon this earth, one such stone falling upon it might, by what we blindly call *natural* causes, lead to its becoming covered with vegetation. I am fully conscious of the many scientific objections which may be urged against this hypothesis, but I believe them to be all answerable. I have already taxed your patience too severely to allow me to think of discussing any of them on the present occasion. The hypothesis that life originated on this earth through moss-grown fragments from the ruins of another world may seem wild and visionary; all I maintain is that it is not unscientific.

From the earth stocked with such vegetation as it could receive meteorically, to the earth teeming with all the endless variety of plants and animals which now inhabit it, the step is prodigious; yet, according to the doctrine of continuity, most ably laid before the Association by a predecessor in this chair (Mr. Grove), all creatures now living on earth have proceeded by orderly evolution from some such origin. Darwin concludes his great work on "The Origin of Species" with the following words:—"It is interesting to contemplate an entangled bank clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other, and dependent on each other in so complex a manner, have all been produced by laws acting around us."

There is grandeur in this view of life with its several powers, having been originally breathed by the Creator into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning, endless forms, most beautiful and most wonderful, have been and are being evolved." With the feeling expressed in these two sentences I most cordially sympathise. I have omitted two sentences which come between them, describing briefly the hypothesis of "the origin of species by natural selection," because I have always felt that this hypothesis does not contain the true theory of evolution, if evolution there has been, in biology. Sir John Herschel, in expressing a favourable judgment on the hypothesis of zoological evolution, with, however, some reservation in respect to the origin of man, objected to the doctrine of natural selection, that it was too like the Laputan method of making books, and that it did not sufficiently take into account a continually guiding and controlling intelligence. This seems to me a most valuable and instructive criticism. I feel profoundly convinced that the argument of design has been greatly too much lost sight of in recent zoological speculations. Reaction against the frivolities of teleology, such as are to be found, not rarely, in the notes of the learned commentators on Paley's "Natural Theology," has, I believe, had a temporary effect in turning attention from the solid and irrefragable argument so well put forward in that excellent old book. But overpoweringly strong proofs of intelligent and benevolent design lie all around us; and if ever perplexities, whether metaphysical or scientific, turn us away from them for a time, they come back upon us with irresistible force, showing to us, through nature, the influence of a free will, and teaching us that all living beings depend on one ever-acting Creator and Ruler.

Section B.

ADDRESS
TO THE
CHEMICAL SECTION.

AUGUST 3, 1871.

By Dr. ANDREWS, F.R.S.

GENTLEMEN,—

Amidst the vicissitudes to which scientific theories are liable, it was scarcely to be expected that the discarded theory of phlogiston should be resuscitated in our day, and connected with one of the most important generalisations of modern science. The phlogistic theory, elaborated nearly two hundred years ago by Becher and Stahl, was not, it now appears, wholly founded in error; on the contrary, it was an imperfect anticipation of the great principle of energy, which plays so important a part in physical and chemical changes. The disciple of phlogiston, ignorant of the whole history of chemical combination, connected, it is true, his phlogiston with one only of the combining bodies, instead of recognising that it is eliminated by the union of all. "There can be no doubt," says Dr. Crum Brown, who first suggested this view, "that potential energy is what the chemists of the 17th century meant when they spoke of phlogiston." "Phlogiston and latent heat," playfully remarks Volhard, "which formerly opposed each other in so hot a combat, have entered into a peaceful compact, and, to banish all recollection of their former strife, have assumed in common the new name of energy." But, as Dr. Odling well remarks, "in interpreting the phlogistic writings by the light of modern doctrine, we are not to attribute to their authors the precise notion of energy which now prevails. It is only contended that the phlogistians had, in their time, possession of a real truth in nature, which altogether lost sight of in the intermediate period has since crystallised out in a definite form."

But, whatever may be the true value of the Stahlian views, there can be no doubt that the discoveries which have shed so bright a lustre round the name of Black mark an epoch in the history of science, and gave a mighty impulse to human progress. A recent attempt to ignore the labours of Black and his great contemporaries, and to attribute the foundation of modern chemistry to Lavoisier alone, has already been amply refuted in an able inaugural address, delivered a short time ago from the chair formerly occupied by Black. The statements of Dr. Crum Brown may, indeed, be confirmed on the authority of Lavoisier himself. Through the kindness of Dr. Black's representatives, I have been permitted to examine his correspondence, which has been carefully preserved, and I have been so fortunate as to find in it three original letters from Lavoisier to Dr. Black. They were written in 1789 and 1790, and they appear to comprise the whole of the correspondence on the part of Lavoisier which passed between those distinguished men. Some extracts from these letters were published soon after Dr. Black's death by his friends, Dr. Adam Ferguson and Dr. Robison, but the letters themselves, as far as I know, have never appeared in an entire form; I will crave permission to have them printed as an appendix to this address. Lavoisier, it will be seen, addresses Black as one whom he was accustomed to regard as his master, and whose discoveries had produced important revolutions in science. It may, indeed, be said with truth that Lavoisier completed the foundation on which the grand structure of modern chemistry has since arisen; but Black, Priestley, Scheele, and Cavendish were before Lavoisier, and their claims to a share in the great work are not inferior to those of the illustrious French chemist. Among the questions of general chemistry, few are

RING VORTICES IN WATER

HENRY DEACON.

WIDNES, 25TH JULY

1871.

more interesting, or have of late attracted more attention, than the relations which subsist between the chemical composition and refractive power of bodies for light. Newton, it will be remembered, pointed out the distinction between the refractive power of a medium and its refractive index, and gave for the former the expression—

$$\frac{\mu - 1}{d},$$

where μ is the refractive index and d the density of the refracting medium. Sir J. Herschel, anticipating later observations, remarked, in 1830, that Newton's function only expresses the intrinsic refractive power on the supposition of matter being infinitely divisible, but that, if material bodies consist of a finite number of atoms, differing in weight for different substances, the intrinsic refractive power of the atoms of any given medium will be the product of the above function by the atomic weight. The same remark has since been made by Bertholet. Later observations have led to an important modification in the form of Newton's function. Beer showed that the experiments of Biot and Arago, as well as those of Dulong, on the refractive power of gases, agree quite as well with a simpler expression as with that given by Newton; and Gladstone and Dale proposed, in 1863, the formula—

$$\frac{\mu - 1}{d}$$

as expressing more accurately than any other, the results of their experiments on the refractive power of liquids. The researches of Landolt and Wüllner have fully confirmed the general accuracy of the new formula. An important observation, made about twenty years ago by Delffs, has been the starting-point for all subsequent investigations on this subject. Delffs remarked that the refractive indices of the compound ethers increase with the atomic weight, and that isomeric ethers have the same refractive indices. The later researches of Gladstone and of Landolt have, on the whole, confirmed these observations, and have shown that the specific refractive power depends chiefly on the atomic composition of the body, and is little influenced by the mode of grouping of the atoms. These inquiries have gone further, and have led to the discovery of the refraction equivalents of the elements. By comparing the refractive power of compound bodies differing from one another by one or more atoms of the same element, Landolt succeeded in obtaining numbers which express the refraction equivalents of carbon, hydrogen, and oxygen, and corresponding numbers have been obtained for other elements by Gladstone and Haagen. The whole subject has been recently discussed and enriched with many new observations in an able memoir by Gladstone. As might be expected in so novel and recondite a subject, some anomalies occur which are difficult to explain. Thus hydrogen appears in different classes of compounds with at least two refraction equivalents, one three times as great as the other, and the refraction equivalents of the aromatic compounds and their derivatives, as given by observation, are in general higher than the calculated numbers.

A happy modification of the ice calorimeter has been made by Bunsen. The principle of the method—to use, as a measure of heat, the change of volume which ice undergoes in melting—had already occurred to Herschel, and, as it now appears, still earlier to Hermann; but their observations had been entirely overlooked by physicists, and had led to no practical result. Bunsen has, indeed, clearly pointed out that the success of the method depends upon an important condition which is entirely his own. The ice to be melted must be prepared with water free from air, and must surround the source of heat in the form of a solid cylinder, frozen artificially *in situ*. Those who have worked on the subject of heat know how difficult it is to measure absolute quantities with certainty, even where relative results of great accuracy may be attained.

The ice calorimeter of Bunsen will therefore be welcomed as an important addition to our means of research. Bunsen has applied his method to determine the specific heats of ruthenium, calcium, and indium, and finds that the atomic weight of indium must be increased by one-half in order to bring it into conformity with the law of Dulong and Petit. He has also made a new determination of the density of ice, which he finds to be 0.9167.

In a Report on the Heat of Combination which was made to this Association in 1849, the existence of a group of isothermal bases was pointed out. "As some of the bases—potash, soda, baryta, strontia—" it was remarked "form what we may, perhaps, designate an isothermal group, such bases will develop the same, or nearly the same, heat in combining with an acid, and no heat will be disengaged during their mutual displacements." The latest experiments of Thomsen have given a remarkable extension to this group of isothermal bases. He finds that the hydrates of lithium, thallium, calcium, and magnesium produce, when all corrections are made, the same amount of heat, on being neutralised by sulphuric acid, as the four bases before mentioned. The hydrate of tetra-methyl-ammonium belongs to the same class of bases. Ethylamin, on the other hand, agrees with ammonia, which, as has been long known, gives out less heat in combining with the acids than potash or soda. An elaborate investigation of the amount of heat evolved in the combustion of coal of different kinds has been made by Scheurer-Kestner and Meunier, accompanied by analyses of the coal. Coal rich in carbon and hydrogen disengages more heat in burning than coal in which those elements are partially replaced by oxygen. After deducting the cinders, the heat produced by the combustion of 1 grm. of coal varied from 8215 to 9622 units.

Tyndall has given an extended account of his experiments on the action of a beam of strong light on certain vapours. He finds that there is a marked difference in the absorbing power of different vapours for the actinic rays. Thus the nitrite of amyl in the state of vapour absorbs rapidly the rays of light competent to decompose it, while iodide of allyl in the same state allows them freely to pass. Morren has continued these experiments in the South of France, and among other results he finds that sulphurous acid is decomposed by the solar beam.

Roscoe has prosecuted the photo-chemical investigations which Bunsen and he began some years ago. For altitudes above 10° the relation between the sun's altitude and the chemical intensity of light is represented by a straight line. Till the sun has reached an altitude of about 20°, the chemical action produced by diffused daylight exceeds that of the direct sun-light; the two actions are then balanced; and at higher elevations the direct sun-light is superior to the diffused light. The supposed inferiority of the chemical action of light under a tropical sun to its action in higher latitudes proves to be a mistake. According to Roscoe and Thorpe, the chemical intensity of light at Para under the equator in the month of April is more than three times greater than at Kew in the month of August.

Hunter has given a great extension to the earlier experiments of Saussure on the absorptive power of charcoal for gases. Cocoa-nut charcoal, according to Hunter's experiments, exceeds all other varieties of wood-charcoal in absorptive power, taking up, at ordinary pressure, 170 volumes of ammonia, and 69 of carbonic acid. Methylic alcohol is more largely absorbed than any other vapour at temperatures from 90° to 127°; but, at 159°, the absorption of ordinary alcohol exceeds it. Cocoa-nut charcoal absorbs 44 times its volume of the vapour of water at 127°. The absorptive power is increased by pressure.

Last year two new processes for improving the manufacture of chlorine attracted the attention of the section, one of these has already proved to be a success, and I am glad to be able to state that Mr. Deacon has recently overcome certain difficulties in his method, and has obtained

a complete absorption of the chlorine. May we hope to see oxygen prepared by a cheap and continuous process from atmospheric air? With baryta the problem can be solved very perfectly, if not economically. Another process is that of Tessié de Mothay, in which the manganate of potassium is decomposed by a current of superheated steam and afterwards revived by being heated in a current of air. A company has lately been formed in New York to apply this process to the production of brilliant house light. A compound Argand burner is used having a double row of apertures,—the inner row is supplied with oxygen, the outer with coal-gas or other combustible. The applications of pure oxygen, if it could be prepared cheaply, would be very numerous, and few discoveries would more amply reward the inventor. Among other uses it might be applied to the production of ozone free from nitric acid by the action of the electrical discharge, and to the introduction of that singular body in an efficient form into the arts as a bleaching and oxidising agent. Tessié de Mothay has also proposed to prepare hydrogen gas on the large scale by heating hydrate of lime with anthracite.

We learn from the history of metallurgy that the valuable alloy which copper forms with zinc was known and applied long before zinc itself was discovered. Nearly the same remark may be made at present with regard to manganese and its alloys. The metal is difficult to obtain, and has not in the pure state been applied to any useful purpose; but its alloys with copper and other metals have been prepared and some of them are likely to be of great value. The alloy with zinc and copper is used as a substitute for German silver, and possesses some advantages over it. Not less important is the alloy of iron and manganese prepared according to the process of Henderson by reducing in a Siemens's furnace a mixture of carbonate of manganese and oxide of iron. It contains from 20 to 30 per cent of manganese, and will doubtless replace to a large extent the spiegeleisen now used in the manufacture of Bessemer steel.

The classical researches of Roscoe have made us acquainted for the first time with metallic vanadium. Berzelius obtained brilliant scales which he supposed to be the metal by heating an oxychloride in ammonia, but they have proved to be a nitride. Roscoe prepared the metal by reducing its chloride in a current of hydrogen, as a light grey powder, with a metallic lustre under the microscope. It has a remarkable affinity both for nitrogen and silicon. Like phosphorus it is a pentad, and the vanadates correspond in composition to the phosphates, but differ in the order of stability at ordinary temperatures, the soluble tribasic salts being less stable than the tetrabasic compounds.

Sainte-Claire Deville, in continuation of his researches on dissociation, has examined the conditions under which the vapour of water is decomposed by metallic iron. The iron, maintained at a constant temperature, but varying in different experiments from 150° C. to 1600° C., was exposed to the action of the vapour of water of known tension. It was found that for a given temperature the iron continued to oxidise till the tension of the hydrogen formed reached an invariable value.

In these experiments as Deville remarks, the iron behaves as if it emitted a vapour (hydrogen) obeying the laws of hygrometry. An interesting set of experiments has been made by Lowthian Bell on the power possessed by spongy metallic iron of splitting up carbonic oxide into carbon and carbonic acid, the former being deposited in the iron. A minute quantity of oxide of iron is always found in this reaction.

The fine researches of Graham on the colloidal state have received an interesting extension by Reynolds's discovery of a new group of colloid bodies. A solution of mercuric chloride is added to a mixture of acetone and a dilute solution of potassium hydrate till the precipitate which at first appears is re-dissolved, and the clear liquid poured upon a dialyser which floated upon water. The composition of

the colloid body thus obtained in the anhydrous state was found to be $[(CH_3)_2CO]_2Hg_3O_3$. The hydrate is regarded by Reynolds as a feeble acid, even more readily decomposed than alkaline silicates. A solution containing only five per cent forms a firm jelly when heated to 50° C. Analogous compounds were formed with the higher members of the fatty ketone series. In the same direction are the researches of Marcet on Blood, which he finds to be a strictly colloid fluid containing a small proportion of diffusible salts.

In organic chemistry the labours of chemists have been of late largely directed to a group of hydrocarbons which were first discovered among the products of the destructive distillation of coal or oil. The central body round which these researches have chiefly turned is benzol, whose discovery will always be associated with the name of Faraday; with this body naphthaline and anthracene form a series, whose members differ by C_6H_2 , and their boiling-points by about 140°. The recent researches of Liebermann have proved, as was before suspected, that chrysene is a fourth member of the same series. I may add that ethylene which boils at about -70° corresponds in composition and boiling-point to a lower member of the same series. Kekulé propounded some time ago with great clearness the question as to whether the six atoms of hydrogen in benzol are equivalent, or, on the contrary, play dissimilar parts. According to the first hypothesis, there can be only one modification of the mono- and penta- derivatives of benzol; while three modifications of the bi- tri- and tetra- derivatives are possible. On the second hypothesis, two modifications of the mono-derivatives are possible and in general a much larger number of isomeric compounds than on the first hypothesis. Such is the problem which has of late occupied the attention of some of the ablest chemists of Germany, and has led to a large number of new and important investigations. The aromatic hydrocarbons, toluol, xylol, &c., which differ from one another by CH_2 have been shown by Fittig to be methyl derivatives of benzol. According to the first of the two hypotheses to which I have referred only one benzol and one methyl benzol (toluol) are possible, and accordingly no isomeric modifications of these bodies have been discovered. But the three following members of the series ought each to be capable of existing in three distinct isomeric forms. The researches of Fittig had already established the existence of two isomeric compounds having the formula C_8H_{10} ,—methyl-toluol obtained synthetically from toluol, and isoxylol prepared by the removal of an atom of methyl from the mesitylene of Kane. The same chemist has since obtained the third modification—orthoxylol—by the decomposition of the paraxylic acid. These three isomeric hydrocarbons may be readily distinguished from one another by the marked difference in the properties of their tri-nitro compounds, and also by their different behaviour with oxidising agents. Other facts have been adduced in support of the equality or homogeneity of position of the hydrogen atoms in benzol. Thus Hübner and Alsborg have prepared aniline, a mono-derivative from different bi-derivatives, and have always obtained the same body. The latest researches on this subject are those of Richter.

Baeyer has prepared artificially picoline, a base isomeric with aniline, and discovered by Anderson in his very able researches on the pyridine series. Of the two methods described by Baeyer, one is founded on an experiment of Simpson in which a new base was obtained by heating tribromallyl with an alcoholic solution of ammonia. By pushing further the action of the heat, Baeyer succeeded in expelling the whole of the bromine from Simpson's base in the form of hydrobromic acid and in obtaining picoline. The same chemist has also prepared artificially colidine, another base of the pyridine series. To this list of remarkable synthetical discoveries, another of the highest interest has lately been added by Schiff—the preparation of artificial coniine. He obtained it by the action of ammonia on butyric aldehyde (C_4H_8O). The artificial base

has the same composition as conine prepared from hemlock. It is a liquid of an amber-yellow colour, having the characteristic odour and nearly all the usual reactions of ordinary conine. Its physiological properties, so far as they have been examined, agree with those of conine from hemlock, but the artificial base has not yet been obtained in large quantity nor perfectly pure.

Valuable papers on alizarine have been published by Perkin and Schunck. The latter has described a new acid—the anthraflavic—which is formed in the artificial preparation of alizarine. Madder contains another colouring principle, purpurine, which like alizarine yields anthracene when acted on by reducing agents, and has also been prepared artificially. These colouring principles may be distinguished from one another, as Stokes has shown by their absorption-bands, and Perkin has lately confirmed by this optical test the interesting observation of Schunck that finished madder prints contain nothing but pure alizarine in combination with the mordant employed.

Hofmann has achieved another triumph in a department of chemistry which he has made peculiarly his own. In 1857 he showed that alcohol bases, analogous to those derived from ammonia, could be obtained by replacement from phosphuretted hydrogen; but he failed in his attempts to prepare the two lower derivatives. These missing links he has now supplied, and has thus established a complete parallelism between the derivatives of ammonia and of phosphuretted hydrogen. The same able chemist has lately described the aromatic cyanates, of which one only—the phenylic cyanate ($\text{CO}, \text{C}_6\text{H}_5, \text{N}$)—was previously known, having been discovered about twenty years ago by Hofmann himself. He now prepares this compound by the action of phosphoric anhydride on phenylurethane, and by a similar method he has obtained the tolylic, xylylic, and naphthyl cyanates.

Stenhouse had observed many years ago, that when aniline is added to furfural, the mixture becomes rose-red, and communicates a fugitive red stain to the skin, and also to linen and silk. He has lately resumed the investigation of this subject, and has obtained two new bases, furfuraniline and furfuraluidine, which like rosaniline form beautifully coloured salts, although the bases themselves are nearly colourless or of a pale brown colour. The furfuraniline hydrochlorate ($\text{C}_7\text{H}_{10}\text{O}_2\text{N}_2\text{Cl}$) is prepared by adding furfural to an alcoholic solution of aniline hydrochlorate, containing an excess of aniline. We have also from Stenhouse a new contribution to the history of orcin, in continuation of his former masterly researches on that body. He has prepared the trinitro-

a powerful acid, having many points of resemblance to picric acid. In connection with another research of Stenhouse made many years ago, it is interesting to find his formula for euxanthone, which was also that of Erdmann, confirmed by the recent experiments of Baeyer.

The interesting work of Dewar on the oxidation of picoline must not be passed over without notice. By the action of the permanganate of potassium on that body, he has obtained a new acid, which bears the same relation to pyridine that phthalic acid does to benzol. Thorpe and Young have published a preliminary notice of some results of great promise, which they have obtained by exposing paraffin to a high temperature in closed vessels. By this treatment it is almost completely resolved into liquid hydrocarbons, whose boiling-points range from 18°C . to 300°C .: those boiling under 100° have been examined and consist chiefly of olefines. In connection with this subject it may be interesting to recall the experiments of Pelouze and Cahours on the Pennsylvanian oils, which proved to be a mixture of carbohydrogens belonging to the marsh gas series.

An elaborate exposition of Berthelot's method of transforming an organic compound into a hydrocarbon containing a maximum of hydrogen has appeared in a

connected form. The organic body is heated in a sealed tube with a large excess of a strong solution of hydriodic acid to the temperature of 275° . The pressure in these experiments Berthelot estimates at 100 atmospheres, but apparently without having made any direct measurements. He has thus prepared ethyl hydride (C_2H_6) from alcohol, aldehyde, &c.; hexyl hydride (C_6H_{14}) from benzol. Berthelot has submitted both wood charcoal and coal to the reducing action of hydriodic acid, and among other interesting results he claims to have obtained in this way oil of petroleum.

By the action of chloride of zinc upon codeia, Matthiessen and Burnside have obtained apocodeia, which stands to codeia in the same relation as apomorphia to morphia, an atom of water being abstracted in its formation. Apocodeia is more stable than apomorphia, but the action of reagents upon the two bases is very similar. As regards their physiological action, the hydrochlorate of apocodeia is a mild emetic, while that of apomorphia is an emetic of great activity. Other bases have been obtained by Wright by the action of hydrobromic acid on codeia. In two of these bases, bromotetracodeia and chlorotetracodeia, four molecules of codeia are welded together so that they contain no less than 72 atoms of carbon. They have a bitter taste, but little physiological action. The authors of these valuable researches were indebted to Messrs. Macfarlane for the precious material upon which they operated.

We are indebted to Crum Brown and Fraser for an important work on a subject of great practical as well as theoretical interest, the relation between chemical constitution and physiological action. It has long been known that the ferrocyanide of potassium does not act as a poison on the animal system; and Bunsen has shown that the kakodylic acid, an arsenical compound, is also inert. Crum Brown and Fraser find that the methyl compounds of strychnia, brucia, and thebaia, are much less active poisons than the alcaloids themselves, and the character of their physiological action is also different. The hypnotic action of the sulphate of methyl-morphium is less than that of morphia. But a reverse result occurs in the case of atropia, whose methyl and ethyl derivatives are much more poisonous than the salts of atropia itself.

Before proceeding to the subject of fermentation, I may refer to Apjohn's chemico-optical method of separating cane sugar, inverted sugar, and grape sugar from one another when present in the same solution, by observing the rotative power of the syrup before and after inversion, and combining the indications of the saccharometer with the results of an analysis of the same syrup after inversion. Heisch's test for sewage in ordinary water is also deserving of notice. It consists in adding a few grains of pure sugar to the water and exposing it freely to light for some hours, when the liquid will become turbid from the formation of a well-marked fungus, if sewage to the smallest amount be present. Frankland has made the important observation that the development of this fungus depends upon the presence of a phosphate, and that if this condition be secured the fungus will appear even in the purest water.

The nature of fermentation, and, in particular, of the alcoholic fermentation, has been lately discussed by Liebig with consummate ability, and his elaborate memoir will well repay a careful perusal. Dr. Williamson has also given a most instructive account of the subject, particularly with reference to the researches of Pasteur, in his recent Cantor lectures. A brief statement of the present position of the question will, therefore, not be out of place here. It is now 34 years since Cagniard de La Tour and Schwann proved, by independent observations, that yeast globules are organised bodies, capable of reproduction by germination; and also inferred, as highly probable, that the phenomena of fermentation are induced by the development or living action of these globules. These views, after having fallen into abeyance, were revived and extended, a few years ago, by Pasteur, whose

able researches are familiar to every chemist. Pasteur, while acknowledging that he was ignorant of the nature of the chemical act, or of the intimate cause of the splitting up of sugar in the alcoholic fermentation, maintained that all fermentations, properly so called, are correlative with physiological phenomena. According to Liebig, the development and multiplication of the yeast plant or fungus is dependent upon the presence and absorption of nutriment which becomes part of the living organism, while, in the process of fermentation, an external action takes place upon the substance, and causes it to split up into products which cannot be made use of by the plant. The vital process and the chemical action, he asserts, are two phenomena which, in the explanation, must be kept separate from one another. The action of a ferment upon a fermentable body he compares to the action of heat upon organic molecules, both of which cause a movement in the internal arrangement of the atoms. The phenomena of fermentation Liebig refers now, as formerly, to a chemico-physical cause, the action, namely, which a substance in a state of molecular movement exercises upon another, of highly complex constitution, whose elements are held together by a feeble affinity, and are to some extent in a state of tension or strain. Baeyer, who considers that in the alcoholic and lactic fermentations one part of the compound is reduced and another oxidised, adopts the view of Liebig, that the molecules of sugar which undergo fermentation do not serve for the nourishment of the yeast plant, but receive an impulse from it. All are, however, agreed that fermentation is arrested by the death of the plant; and even a tendency to the acetous fermentation in wine may be checked, as Pasteur has shown, by heating the wine to a temperature a little below the boiling-point in the vessel in which it is afterwards to be kept.

I regret that the limits of an address like the present forbid me to pursue further this analysis of chemical work. Had they admitted of abridgment, I should gladly have described the elaborate experiments of Gore on hydrofluoric acid and the fluoride of silver. The important researches of Abel on explosive compounds will be fully explained by himself in a lecture with which he has kindly undertaken to favour the Association. Mr. Tomlinson will also communicate to the section some observations on catharism and nuclei, a difficult subject to which he has of late devoted much attention. And I am also informed that we shall have important papers on recent improvements in chemical manufacture.

No one can be more painfully alive than myself to the serious omissions in the historical review I have now read, more particularly in organic chemistry, where it was wholly impossible to grapple with the large number of valuable works which even a few months produce. I cannot, however, refrain from bearing an humble tribute to the great ability and indomitable perseverance which characterise the labourers in the great field of organic chemistry. It would scarcely be possible to conceive any work more intelligently undertaken or more conscientiously performed than theirs, yet much of it, from its abstruse character, receiving little sympathy or encouragement, except from the band of devoted men who have made this subject the chief pursuit of their lives. They will, however, find their reward in the consciousness that they have not lived in vain, but have been engaged, and successfully engaged, in the noble enterprise of extending, for the benefit of the human family, the boundaries of scientific knowledge. Nor is there any real ground for discouragement. Faraday, Graham, Magnus, and Herschel, who have left their impress on this age, were all distinguished chemical as well as physical discoverers; and the relations of the sciences are becoming every day so intimate that the most special research leads often to results of wide and general interest. No one felt this truth more clearly, or illustrated it better in his writings, than our lamented and distinguished friend, Dr. Miller, whose presence used to cheer our meetings, and whose loss we all most sincerely deplore.

EXPERIMENTS ON FORMATION OF RING VORTICES (WITH SECONDARY PHENOMENA) IN WATER.*

By HENRY DEACON, J.P., F.C.S.

IN the course of an experimental research on the motion of fluids, I was very recently working with water very slightly coloured with indigo dissolved in sulphuric acid, projected into spring water, the object being to have both fluids of precisely the same specific gravity. My assistant had prepared the two fluids with a specific gravity bottle in the ordinary laboratory balance, and we were together in a quiet room, with the water quite at rest to commence the research. A phenomenon occurred which I at once said arose from the coloured fluid being the heavier. My assistant referred to his weighings in the laboratory. It occurred to me that if a drop of the coloured water were very gently placed in the perfectly still clear water, the motion of the coloured drop would decide the point; if heavier it would sink. It did sink, but in sinking gave rise to the phenomena now referred to, some of which I hope to succeed in showing you.

To describe what to look for, I refer to the accompanying supplementary plate. Fig. 1 is a ring—a "smoke ring" in miniature. Fig. 2 indicates the commencement of the next change, the formation of nodes, varying much in number and position, influenced by currents in the water, shape of the drop, &c. Fig. 3 shows how, by descending, the nodes begin to develop secondary rings, shown in an advanced state of development in Fig. 4, the centre of each secondary ring being connected with the centre of the one on each side of it by a delicate arch. If coloured solutions are used, and the vessel not too deep and with a flat bottom, this crown-like structure will for a few minutes rest on the bottom, with the arches springing up from circle to circle. Fig. 5 is a rough indication of what frequently happens when the secondary rings and connecting links descend well below the primary rings, and tolerably uniformly. A rather rapid contraction and drawing-up of the tops of the arches takes place; that is, while the lower series of secondary rings continue to descend, the upper part of the structure rapidly descends and contracts. This upward motion lasts but a short time, and then the whole fabric descends altogether. Occasionally, and under circumstances I cannot speak of with certainty, a form is seen of which Fig. 6 is a very feeble illustration. The arches from the secondary rings are here connected by a delicate film; this is contracted into a tube, the upper part of which turns over like a deeply-recurved convolulus. Working with a very attenuated solution of permanganate of potash, the secondary rings resting on the bottom of the beaker, or wholly suspended in the water, it strikingly resembles a living animal, like a sea anemone. As all this structure is formed from one single drop its extreme tenuity can be easily imagined. The resemblance of these structures to organisms is more than in form. Whilst they are growing they are, so to say, "alive," bright colours and clearly-defined objects. When they cease to grow their "life" ceases too, they become dull, flaccid, nebulous,—they quickly dissolve into the surrounding space,—they die. In Fig. 7 I have attempted to show the motion of the "rings" themselves, and the cause to which I ascribe the phenomena indicated in Figs. 5 and 6. The motion of the "ring" is the same as that of the "smoke-rings," reversed, of course, because these "rings" descend instead of ascend. In water, this motion ceases almost entirely, and the whole "ring" descends bodily. In this descent water is displaced, and a current due to this displacement flows upwards through the "ring" centre, as shown by the long arrows. There is, of course, an ascending current outside the ring, but this is spread

* Read before the British Association, Edinburgh Meeting, Section B.

over a larger area, whilst that inside the ring is more concentrated and of greater velocity; it therefore overcomes the outside induced current so far as these phenomena are concerned. Where the secondary "rings" and their connecting arches descend, they obstruct the access of the water to the internal ascending column. A result ensues similar to that of the water-ram. The column continues its motion, its viscosity causes it to elongate, and diminishes in diameter, thus elongating and contracting the adjacent parts of the "ring." The top is re-curved by this column of water beating against the still water above it, in just the same way that the "ring" itself is formed by the drop in motion beating against the water at rest. Fig. 8 feebly represents one of the ordinary phenomena when a faint stream descends, the end is re-curved, and a ring surrounds the re-curved part, just like a delicate fungus upside down. Water holding solid matters in suspension serve well to illustrate these rings and secondary rings, but is, I think, unsuitable for the succeeding forms. I prefer coloured solutions for the remainder of the phenomena. A very brief interval has elapsed since I first saw these rings, and very numerous avocations preclude the idea of my doing much more with them. One thought in connection with them has occurred to me: secondary rings give rise to tertiary rings, and these to a fourth series, and perhaps more.

May not this tendency to form, from merely straight currents, structures at intervals in planes at right angles to the current, throw light on the formation of clouds in strata? A vertical ascending current of vapour develops a structure in a horizontal plane, that is the first stratum of clouds. From this structure vertical columns again arise, and secondary, and, in turn, other structures are formed at various heights, but each in distinct planes. To obtain these rings to perfection, the water must be perfectly still, the drop as nearly the same specific gravity as possible, but the heavier of the two. The dropping-tube, or rod, must deliver a nicely-shaped drop, and this must enter the water quietly and with very little impetus. Some impetus it must have, but too much breaks up the drop, sometimes giving rise to a mere cloud, and sometimes to two or more very small rings, and more or less figures like Fig. 8. With solutions of rather higher specific gravity from dissolved substances the motion of the rings is more violent, but I do not think the phenomena so characteristic. Diffusion comes into play and breaks up the structure.

The secondary phenomena appear to be influenced by the chemical nature of the colouring matter, as illustrated by the different action of the permanganate and indigo solutions, and the secondary rings are always the edge of a thin film of the original drop, never, so far as I have observed, being distinct ring vortices. I should like to see these figures formed from some suitable solution, and illuminated by polarised light or the invisible rays of the spectrum. Somewhat striking experiments could, I think, be devised by having the receiving vessel filled in layers with solutions differing very little from each other in specific gravity, but containing different salts, so that a drop of another kind of solution should, in passing through the different layers, become alternately visible and invisible, or of different colours.

I think these "rings" will serve to illustrate the laws of vortices of motion, as Attwood's machine serves to illustrate some of the laws of bodies in motion. The proportions are preserved in a diminished scale and brought within easy observation. My conviction, based on some very hasty observations, is that phenomena similar to sensitive flames and their congeners can be obtained and studied by the aid of streams of coloured solutions in colourless fluids. That the "rings" are very sensitive to vibrations like those of sound is evidenced by the influence exerted by the diameter and depth of water into which the drop falls. The larger the diameter and the greater the depth, the more complete the series of charac-

teristic transformations. Amongst the possibilities I hope some day to effect with these rings, is their exhibition as solids. Imagine a drop of melted wax, paraffin, sulphur, &c., falling into a suitable solution, and descending into a cold stratum; should we not have a frozen ring?

ON THE ESTIMATION OF SULPHUR BY BARIUM.

By E. F. TESCHEMACHER and J. DENHAM SMITH.

A SOLUBLE salt of barytes, *terra ponderosa*, appears to have been used from the beginning of the art of chemical analysis as the most trustworthy agent for ascertaining the existence, and determining the amount of sulphuric acid present in solutions. The delicacy of the test, and the insolubility of the resulting sulphate, seemed to leave nothing to be desired in the reliance to be placed on the results yielded by barytes when used in analysis for estimating sulphuric acid.

As the methods of oxidation of the sulphides, and the conversion of their sulphur into sulphuric acid, were discovered, the extension of the use of barytes to the estimation of sulphur soon took place; and, until a comparatively recent period, no doubt was entertained that the weight of the sulphate of barytes yielded by any given salt or solution would indicate, unerringly and with exactness, the amount of sulphur present in a sulphide, whether factitious or native. The reliance placed upon the accuracy of a determination of sulphuric acid or sulphur by means of sulphate of barytes precipitated from a dilute acid and boiling solution, allowed to cool, and the precipitate copiously washed with hot water, in the first instance acidified with hydrochloric acid, when dried and ignited—was, within the memory of many, absolute; and the manuals of analysis of the period we refer to do not even hint at the possibility of error. Yet it is well-nigh certain that in every instance of such a determination of sulphur or sulphuric acid, the results are not trustworthy and only approximate to accuracy, and this chiefly because the combining equivalent of barium was then reckoned at some two per cent higher than now, 70 instead of 68.50, so that error in the weight of the barytic sulphate was, in great measure, compensated by the error in the equivalent.

With the advance in the art of chemical analysis, it was found that precipitated sulphate of barytes had a marked tendency to carry down with it variable quantities of other salts contained in the solution, such as those of soda, potash, barytes, magnesia, iron, copper, &c.; and the later treatises on analysis give detailed directions to purify the precipitated sulphate from the adherent salts, directions which, even if efficient, are tedious and troublesome, and, at the best, leave the results still subject to doubts of its accuracy. Hence there has been a tendency manifesting itself to prefer volumetric to gravimetric methods for estimating sulphur; and these have undoubtedly been attended with greater accuracy than formerly, despite the objections inherent in all volumetric methods.

Of late years, since the general adoption of pyrites for alkali-making in lieu of brimstone, accuracy in the estimation of sulphur has become a matter of some commercial importance; and, as in our practice we know but too well how variable are the results certified to as having been obtained by professed analysts from carefully-prepared and similar samples of pyrites, which we have good grounds for regarding as identical samples, we hope that some remarks on the difficulties attending an accurate estimation of sulphur by barium, and the details of a rapid and reliable method when applied to pyrites, long practised by us, may prove acceptable to many interested in the subject, and, we would fain hope, put an end to the gross errors now so frequently brought to our notice in the estimation of sulphur in pyrites, a subject which has been

lately dwelt-upon by the President of the Chemical Society of Newcastle-on-Tyne, and reported in the last volume of the CHEMICAL NEWS, p. 57, and his remarks are so much to the point that we quote them *in extenso* :—

"I beg to draw your attention to this tabulated result of seven different samples of sulphur ore (pyrites), by three different chemists, each having the same sample to operate on.

No.	Sulphur per cent.			Difference between A and B.		Difference between A and C.	
	A.	B.	C.				
1.	38·80	38·00	40·20	..	0·80	..	1·40
2.	40·90	40·90	42·70	..	—	..	1·80
3.	39·60	39·70	41·10	..	0·50	..	1·50
4.	39·30	39·50	40·70	..	0·20	..	1·40
5.	41·60	41·40	43·50	..	0·20	..	1·90
6.	38·20	38·00	40·00	..	0·20	..	1·80
7.	39·70	39·20	41·10	..	0·50	..	1·40
Average 0·34							1·60

"You will observe that between A and B, there is comparatively little difference, the maximum amount being 0·80, while between A and C the maximum difference is 1·90; the average difference between A and B is only 0·34, but the average difference between A and C is 1·60.

"I ought to mention that A and B are local chemists, but residing and working in different parts of the district, and acting quite independently of each other, and that C is a metropolitan chemist; also that A and C are professional chemists, B is chemist in the laboratory of the purchasers of the ores."

Probably it would be found on inquiry that different methods of estimating the sulphur in the foregoing experiments have been adopted by the local and the metropolitan chemists above-mentioned; as, whilst the average difference between the professional chemists amounts to 1·60 per cent of sulphur, this rises to almost 2 per cent, if the results of the purchasers' chemist are compared with those of the metropolitan analyst.

In estimating the sulphur in pyrites by the weight of the sulphate of barytes obtained, it must have struck every analyst that the resulting sulphate, after ignition, is usually stained with iron oxide; and also it may have been noticed by him, when he has endeavoured to prevent a deep stain by washing the precipitated sulphate with but moderately diluted hot hydrochloric acid previously to collecting the precipitated on a filter, and has kept the filtrate and washings for a day or two, that the sides and bottom of the beaker have been covered with a film, gradually deposited by the previously clear and bright filtrate; but we are unaware that this fact has been commented on, or met with the notice it deserves, proving, as it does, that *sulphate of barytes is noticeably soluble in hot and but moderately diluted hydrochloric acid*. Here, we doubt not, is one source of the differences spoken of in the estimation of sulphur in pyrites by different chemists; nor is this source of error a slight one, especially when we remember that it is the practice of many to operate on but small amounts of pyrites, so that any analytic error is considerably multiplied and augmented when the results are reported *per centum*. True it is that the solubility of the sulphate in hydrochloric acid has already been pointed out, but the importance of this fact has been underrated, and esteemed as but little likely to affect the estimation of sulphur by barium. On the other hand, the adhesion of chloride of barium to the precipitated sulphate is also known, but this does not appear to have excited the same attention of writers on the subject as the analogous case of the nitrate of barytes, which most markedly affects the weight of the barytic sulphate. Thus, 108·60 grs. of crystallised sulphate of iron, equal to 91 grs. of sulphates of barytes, when oxidised in the usual way, but the excess of nitric acid not expelled, yielded 94·20 grs. of sulphate of barytes, being an excess of 3·20 grs. beyond the calculated weight. These sources of error may, however, be

somewhat compensated by a partial reduction of the sulphate during ignition, for it must be remembered that the barytic is one of the most readily decomposed of the earthy sulphates, by ignition in contact with deoxidising agents, so that evidence of the presence of barytes on treating the ignited sulphate by water or dilute acid must not be regarded as proving that nitrate or chloride has adhered to the precipitate. Thus, some precipitated and ignited sulphate of barytes, when treated first with water and then with diluted hydrochloric acid, washed and re-ignited, and again treated with water and dilute acid, six consecutive times, yielded each time traces of chlorine and barytes to water only, and a considerable amount of barytes to the dilute acid, proving that sulphate of barytes is sensibly reduced when ignited to redness in the usual manner. From the foregoing, it will be seen that pitfalls abound in the estimation of sulphur by barium.

We had long since found that one requisite, and that an essential one, in the correct estimation of sulphur, was to obtain a soluble sulphate of stable composition, the basic element of which should not be adherent to the barytic sulphate; and this was found in crystallised sulphate of iron. Sulphate of potash seemingly offered a better fixed standard, as this salt is anhydrous, and is readily procured in a state of absolute purity, but long experience had shown us that no salt yielded more discordant results with barytes than sulphate of potash. The sulphate of iron we speak of has, of late years, become an article of commerce, and occurs in hard, separate, and small crystals, very uniform in size. This is crushed to the size of hemp-seed, and the dust and smaller fragments sifted out; then washed by shaking with repeated portions of methylated spirit, and rapidly dried on bibulous paper, when a brilliant hard salt of a light beryl-colour, free from interposed water or per-salt is obtained, which is perfectly stable and unvarying in composition. There is a further advantage attached to the use of crystallised sulphate of iron, viz., that a considerable weight of this salt indicates but a small amount of sulphur, 108·60 grs. being equal to 12·50 grs. of sulphur, the amount of sulphur, or thereabouts, we find to be the best and most reliable for working on in ordinary practice with pyrites; and, moreover, when the solution of this salt is oxidised, the result is identical with that produced by the oxidation of pyrites.

A series of experiments was made by dissolving 108·60 grs. of the above described crystallised sulphate of iron in 2000 grs. of water, acidifying the solution with 500 measured grs. of hydrochloric acid, sp. gr. 1·160; and, precipitating this solution by an equally dilute and acidified solution of chloride of barium, the latter always in moderate excess, and both solutions boiling at the time of precipitation, the subjoined weights of sulphate of barytes were obtained :—

No. 1.	91·90 grs. of sulphate of barytes.
" 2.	92·90 " " "
" 3.	92·10 " " "
" 4.	91·25 " " "
" 5.	90·80 " " "
" 6.	91·90 " " "
" 7.	91·30 " " "
" 8.	91·50 " " "
" 9.	91·60 " " "

The calculated weight, or that which ought to have been obtained, in each instance being 91·02, practically 91 grs. of sulphate of barytes.

(To be continued).

EXPERIMENTS ON CHEMICAL DYNAMICS.*

By J. H. GLADSTONE, F.R.S., and ALFRED TRIBE, F.C.S.

THE authors had recently communicated a paper to the Royal Society in which they investigated somewhat minutely what takes place when a plate of one metal, such as copper, is immersed in a solution of a salt of another metal, such as nitrate of silver. They had shown that, while the silver was being deposited on the copper, an actual passage of the nitric element towards the more positive metal occurs, causing the formation of a dense solution of nitrate of copper inside the crystalline deposit, and a consequent downward current, and at the same time an upward current of almost pure water from the tips of the crystals. They had shown, also, that with solutions of different strengths the chemical action in a given period (say ten minutes) is not in direct proportion to the strength; but, *ceteris paribus*, twice the strength gives three times the chemical decomposition. This augmentation had been attributed to an increased conduction of the stronger liquid. In the present paper, the authors exhibited these phenomena in a dissected form, and carried the observations still further.

Instead of the silver crystals being allowed to grow from the copper into the nitrate of silver solution, two separate plates were taken, one of copper and the other of silver. The copper plate was immersed in nitrate of copper, and the silver plate in nitrate of silver, while the two metals were connected by a wire, and the two liquids were connected by a porous cell. Silver crystals were gradually formed upon the silver plate, while the copper was dissolved; and at the end of some hours it was found that all the silver had been removed from solution, and that the loss of the copper plate was almost exactly what might be calculated from the amount of nitrate of silver originally placed in the other cell. The actual numbers were—*theoretical*, 0.412; *actual*, 0.402. The copper nitrate was formed in the cell with the copper plate, the sp. gr. of the liquid having risen from 1.015 to 1.047.

A similar experiment was tried with plates of copper and zinc in sulphate of copper and sulphate of zinc, respectively. The result was as before, metallic copper being deposited on the copper plate, and the sulphate of zinc rising in sp. gr. from 1.123 to 1.139.

In order to determine whether the amount of silver deposited depended, not merely on the amount of the silver in solution, but also on the amount of copper salt that bridged over the intervening space, similar experiments were made in which the nitrate of silver was kept constant, but the nitrate of copper was increased by equivalent multiples. It was found that the silver deposited increased with the increase of the copper salt, being about double when the copper salt was seven times as strong, and that the effect of successive additions gradually diminished. This is in strict accordance with other experiments, showing that, when the copper plate is immersed in a mixture of the nitrates of copper and silver, the amount of silver deposited is increased, and increases with each successive addition of copper salt, though in a diminishing ratio.

That this acceleration is not produced by a copper salt only was proved by repeating the experiment with a variety of other nitrates.

The subjoined table shows the results, and indicates, at the same time, that the increased effect does not depend

simply upon the nitric element, which was present in the same quantity in all, but likewise on the nature of the salt.

Size of plate, 3230 sq. m.m.; volume of solution, 72 c.c., containing 2.8 per cent of nitrate of silver; temperature, 18° C.; time, five minutes.

ON A NEW SOURCE OF ELECTRICITY.

By JAMES St. CLAIR GRAY, M.B., C.M., &c.,

Assistant to the Professor of Medical Jurisprudence, Glasgow University.

IN the course of some experiments relative to sulphur and phosphorus, my attention was drawn to their mutual action while in alkaline solutions, and it occurred to me that probably from this there might be derived an electric current.

In order to ascertain this, as well as to determine—should there prove to be such—whether it was constant or not, there was prepared a cell containing a solution of caustic potash in which phosphorus and sulphur, both in sticks, were placed. Within half an hour the phosphorus was reduced to an oily mass, perfectly mobile, occupying the lower part of the cell; the sulphur was not at first affected. The temperature at first rose considerably—about 20°—but this soon passed off, and the solution returned to the temperature of the surrounding medium, varying from 56° to 60° F. During the first six days there was a constant development in small quantity of phosphuretted hydrogen in the spontaneously inflammable form, but after that time, although phosphuretted hydrogen still continued to be evolved, it no longer ignited spontaneously, this being probably due to the simultaneous development of sulphuretted hydrogen, which began to be exhaled in appreciable quantity about this time. At first the sulphur was little affected, but at the end of ten days it was found that at the point of junction of the phosphorus therewith there had occurred considerable loss of substance.

In the solution there were produced sulphite and phosphite, hyposulphite and hypophosphite, and slight traces of sulphate and phosphate of potassium.

At the end of three months the conditions were still much the same; the phosphorus was still fluid and mobile, the sulphur more eroded, the same products present in solution, though increased in quantity and somewhat altered in the ratio which the one salt bore to the other: due allowance being made for increase, the proportion of sulphate and phosphate was greater.

Another cell was prepared on the same principle, and both cells were then submitted to Mr. Hill, one of the assistants in Sir William Thomson's laboratory, to determine the amount of electricity developed, if any. The result far exceeded my expectations, for not only was electricity found to be developed, but a very considerable quantity thereof. The electro-motive force, as registered by Sir William Thomson's electrometer, was found to be 162, which, compared with that of a Daniell's battery, 120, shows a difference in favour of the sulphur and phosphorus of 42°. It was, further, also found that in the cell which had been in opera-

* Read before the British Association, Edinburgh Meeting, Section B.

tion for three months, the reading of the scale was quite the same, so that from this cell there was derived an electric current of considerable intensity which had the advantage of being constant.

Wishing then to obtain again in its solid state the residuum of phosphorus which lay at the bottom of the cell, I removed the rolls of sulphur and the alkaline solution, replacing it by pure water, and washing till free of alkali. The phosphorus, under water, was kept for ten days perfectly undisturbed, but at the end of that time was as mobile as ever. A stick of solid phosphorus was then placed among the fluid mass without inducing solidification; on the other hand, the solid become liquefied in a short time. It was then cooled down to 34° F., but still remained fluid, so that I have it still by me in the same mobile, oily condition without apparently any change occurring, though, since the removal of the alkali, nearly two months have elapsed. To what this is due I cannot say, though, I believe, it depends on the presence of some compound of sulphur and phosphorus, as both are present; though in what proportion I cannot at present state.

I am at present engaged in further observations on this and other allied subjects, the results of which I shall hereafter make known.

ON THE BEHAVIOUR OF SUPERSATURATED SALINE SOLUTIONS WHEN EXPOSED TO THE OPEN AIR.*

By CHARLES TOMLINSON, F.R.S.

It is known that, when a vessel containing a supersaturated saline solution is opened in a room, it immediately crystallises, provided the temperature be not too high. Mr. Tomlinson shows that supersaturated solutions of Glauber's salt (and also of Epsom salt, and of alum) may be exposed to the open air of the country for many hours, and even be taken out of the flasks in clean metal spoons, without crystallising. From a large number of experiments, conducted under various conditions, the following conclusions are drawn:—

1. That a highly supersaturated solution of sodic sulphate may be exposed to the open air of the country in an uncovered flask, and in cloudy weather, for from twelve to twenty hours, without any formation of the ordinary ten-watered salt.
2. That if the temperature fall to 40° F., and under, the modified seven-atom salt is formed at the bottom of the solution, just as in covered vessels.
3. That if the exposed solution suddenly crystallises into a compact mass of needles, a nucleus may always be found in the form of an insect, a speck of soot, a black point of carbon, &c.
4. That if, during the exposure, rain come on, the solution generally crystallises suddenly, in consequence of an active nucleus being brought down. But if the flask be put out *during* heavy rain, when we may suppose all the solid nuclei to have been brought down, the rain-drops, now quite clean, fall into the solution without any nuclear action.
5. That the young and newly-sprouted leaves of trees, such as the gooseberry and currant bushes, have no nuclear action.
6. That, in clear cloudless weather, when the force of evaporation is strong, the solutions, by exposure, produce fine groups of crystals of the ten-atom salt, just as a saturated solution would do if left to evaporate slowly in an open dish.
7. That if the solution, after being exposed to the open air, be brought into a room, it crystallises immediately under the action of aerial nuclei.

ON THE ORIGIN OF THE DIAMOND.*

By the Rev. W. B. CLARKE, M.A., F.G.S.

(Continued from p. 42).

Diamonds in India.

WE may now turn to another quarter. India was renowned as a diamond country long before Brazil; Tavernier mentions diamonds in 1642.

In 1814, Dr. Helyne published some tracts on India, in which he described the diamond mines of Southern India, showing that a conglomerate caps the Cuddapah Hills; and he adds, wherever diamonds are found they are in alluvia and recent deposits in which the rounded pebbles are so numerous as to produce the conglomerate character.

In 1832, Mr. Callinger published in a Calcutta periodical—"Gleanings in Science"—some notes on the geology of the country between Saugor and Mirzapore, in which he mentions the occurrence of diamonds in solid sandstone underlying chlorite slate, and also in a ferruginous agglomerate, of which he gives several localities.

Mr. Newbold in a paper that may be found in the *Athenæum* of June 11, 1843, has described the diamond-bearing gravel of Cuddapah, in Bundelcund, a little south of Golconda.

It holds rounded pebbles of trap, granite, schists derived from beds twenty to forty miles distant, quartz, jasper, siliceous sandstone, and limestone of the vicinity. In it are broken or rolled diamonds; and as the diamond beds are occasionally covered by *Regur*, or black cotton soil (which is also not uncommon in Australia), I consider they are of the same age as the older drift of the Cudgong. But when these materials are cemented at the upper part by *Kunkur*, which is a tufaceous carbonate of lime (very common in some parts of Australia), diamonds are *never* found. In the Nizam's territory, such cemented beds contain bones of the Mastodon.

If the fifth volume of the second series of *Transactions of the Geological Society of London* is a valuable memoir "On the Fossils of the Eastern portion of the great Basaltic district of India," by the late Mr. Malcolmson, which was read in November and December, 1837. In it he alludes to the Cuddepah diamond mines, in the neighbourhood of which is abundance of basalt. He gives also a sketch of the position of the diamond sandstone of Bangnapilly, which is horizontal, vertically jointed, resting on schistose beds underlain by stratified limestone, and surmounted by a diamond-bearing breccia, which is not interstratified, but is a mixture of sandstone and other rocks, rounded and angular. On the opposite side of the valley, according to Colonel Cullen, the sandstone is replaced by a sharp ridge of trap, and on the descent the schist and limestone were found to be capped by a quartzose sandstone. Besides the diamond conglomerate, seams of rock crystal occur, and fine white quartz charged with galena, and with specular, micaceous, and pyritous iron. The slates are occasionally flinty or jaspideous. The base of the whole is the granite of the Carnatic, and this rock is penetrated by many dykes of greenstone. In the diamond sandstone, magnetic iron and corundum are met with. The fossils in the argillaceous limestone are of fresh water origin.

Mr. Malcolmson opposes the idea of Major Franklin, that the diamond rocks belong to the saliferous deposits of England. In this part of Bundelcund, greenstone follows the strike of the so-called *grauwacke* in the bed of the Nerbudda River, and basalt forms the overlying strata, another analogy with the Cudgong diamond district.

Mr. Broderip considered the rocks to be jurassic, and scarcely distinguishable from the white lias of Bath.

As to the saliferous beds, Mr. Malcolmson says, there is not a rock formation in India from granite to recent alluvium in which salt does not exist; and he further states, that the sandstone, covering 800 miles of latitude

* From the Anniversary Address delivered to the Royal Society of New South Wales.

and 400 of longitude, is everywhere above the limestone which Captain Franklin calls *lias*.

In 1853, Mr. Carter, in his "Summary of the Geology of India" (*Bombay Asiat. Soc.*, 1854), also adopts the view that these Bundelcund diamond rocks are jurassic.

D'Archiac (*Progrès*, vol. vii., p. 644) repeats Carter's statements, and puts the diamond-bearing conglomerate with a note of interrogation above the Punnah sandstone, and much above the carbonaceous shales of Kuttra.

I would here wish to remark that these beds must be distinguished from those which hold *glossopteris*, and which paralleled with the African Karoo beds, Mr. Tate (*Q. J.*, xxiii.) in 1867, considered triassic, whilst Dr. Oldham, the experienced and able Superintendent of the Geological Survey of India, agrees with me in assigning them to a palæozoic epoch. But inasmuch as coal may exist in the jurassic or triassic, as well as upper palæozoic formations, the proximity of a coal-bearing formation to the diamond rock leaves the question as to the origin of diamond in such a formation just where it was.

Since the establishment of the Indian Survey, under its present enlightened Superintendent, the Messrs. Blanford and Mr. Theobald have explored large tracts of India, and have given their opinion, in which Dr. Oldham concurs, that the Nagpur, Damoodah, and Talcheer, as well as other Bengal coal-fields, cannot be younger than permian. (*Mem. Ind. Surv.*, vol. i., p. 82). These beds in the Damoodah group hold many species identical with those of our New South Wales coal districts, including the outlying patches on the Cudgong.

The Indian surveyors show that the Mahadeva sandstone (or Bangnapilly rock) surmounts the Damoodah beds, believed to be permian, and that the Talcheer group, which underlies them rests on gneiss, hornblendic gneiss, schist, and quartz schist; and in the Mahanuddi River to the southward of the Talcheer coal-fields, which runs through the basic formations, a small amount of diamonds has been found. Where the Talcheer beds meet the hornblendic rocks by a fault on the Takirra River, and in the Ouli which flows to it from the Mahadeva rocks, gold is occasionally found.

North of this region the great Vindhyan rocks stretch across the country north-north-easterly, being the upper of three groups resting on gneiss and granite. These are described in the second volume of the "Memoirs of the Survey," by Professor H. B. Medlicott; and both he and Dr. Oldham give good reasons for placing the Vindhyan series in connection with the Damoodah, or coal measures, of the Talcheer field, and therefore they are far removed from the Bangnapilly beds belonging to the Mahadeva group to the southward.

Mr. Medlicott shows that the diamond beds are not all of one age, and instances the mines at Punnah, 600 or 700 miles north of Cuddapah, which he places close to the junction of the lower and middle groups of the Vindhyan series, at the northern edge of the Rewah tableland, in the shales, to which latter group they belong. This at once places them far below any possible jurassic or even triassic strata.

The Punnah diamond diggings occupy not more than 20 acres. The diamonds are found in a conglomerate belonging to relics of old spurs and outliers of the tableland. Fine grits among red and green shales, and a few beds of sandstone, constitute the strata.

At Kumerea (another field), the diamond bed is in an incoherent ferruginous sandy earth, of variable thickness and undecided position. To the east it is modified, and near Bridgepur it consists of two feet of conglomeratic sandstone, resting on strong beds of sandstone, and is worked at the surface. The "kukra," or diamond bed, is sometimes an incoherent ferruginous and sandy earth, variable in thickness and position as are the beds with which it is associated. It appeared to Mr. Medlicott to be somewhat of a puzzle where to place the conglomerate among the regular beds, and he considers the ferruginous

element to be subsequent to the deposition. The beds thin out and thicken remarkably. The natives seem to have ascertained the limits of the diamond area, owing probably to the beds dying out. The base of the hills has not been tried.

As to the origin of the diamond, he does not think the stratum in which it is found is its native bed. He saw no diamonds *in situ*, but, from what he learned of the labourers, "*the diamonds came as pebbles with the rest.*" Quartz pebbles of any kind are rare. The most prominent pebbles are subangular red and white shale, and of what Franklin calls "green quartz," which is elsewhere described by Mr. Medlicott as "glazed or semi-vitrified sandstone." Pieces of the calcareo-siliceous bottom rock of the size of boulders occur also: One of the workmen confirmed his opinion, that the occurrence of these pebbles indicated the presence of the gem, and that "*they themselves contained diamonds, and were broken up*" as ore or, rather, as gangue.

In a section just north of the mines, twenty feet of regular beds of cherty and compact limestone rest on 50 feet of alternating sandstone and shale, based on rich sienite; the cherty and jaspery condition of some of the more vitrified beds is shown by another section to be due to a "modifying influence." It is supposed that these beds are the sources of the boulders in the diamond conglomerate. Besides these diggings, the great majority are said to be alluvial.

On the Rewa escarpment, in the Vindhyan region, they are at the heads of valleys descending from the plateau, where kunkery and lateritic clays pass into a mixture of clay, gravel, and boulders, increasing to great angular blocks of sandstone, between which the diamonds are found. Diggings occur also on the slopes. In one place men were seen removing 12 feet of dark brown clayey sand to get at the boulder bed, the base of which is richest.

"The limited distribution of the transported diamonds was more puzzling" to Mr. Medlicott than that of the rock. He thinks there are indications beyond the area that is worked.

The conclusion is, that the open valleys of Rewah are not altogether due to atmospheric and river action; the whole must have been under water when these diamonds were washed into their position. "If," says the author, "the diamond is but a pebble in the conglomerate," then, on the other hand, there is every chance of further discoveries, "since quartz grains of similar size with the diamonds are abundant, and there are other sufficient proofs of the recent submergence of the country."

In the above references there is not as clear a relation as was given in connection with Brazil; but the geology of the region is not in some respects so settled as to determine exactly where, in relation to other countries, the Vindhyan rocks of India belong. Enough, however, has been produced to show that the Mahadeva beds are younger than the Damoodah, which clearly correspond with our own upper coal-measures, and that the Vindhyan beds were faulted and elevated and denuded before the deposition of the Talcheer beds that are still lower than the Damoodah.

Under such circumstances it follows that there is probably no very close connection between diamond beds in India at distant localities, and very little to justify the supposition that all, if any, of the Indian diamond deposits can be exactly synchronous with older pliocene.

I have not yet mentioned two very important and interesting memoirs, by Messrs. Hislop and Hunter, published in the 10th and 11th volumes of the *Quarterly Journal of the Geological Society*, on the geology of the Nagpur territory. Differing in opinion from them as to the age to which they assign what they term the great jurassic formation, which extends over enormous areas, and comprises the coal-fields of Central India and Bengal, I would still accept their statements with the greatest respect. They regard the base of the Peninsula as formed of gneiss, granite, sienite, pegmatite, mica

schist, and quartz; but these are not all of anterior date to the sedimentary formations.

Over these occur the coal-bearing rocks, the upper part of which are the sandstones, partly transmuted, which have been already alluded to, and which other authorities regard as the source of the diamond.

Over these beds comes the lower trap rock, which is compact beneath and vesicular at the top, with cresting patches of nodular trap. These traps enclose in places a thin sedimentary formation of tertiary age, which has an uninterrupted range of 1050 miles in one direction, and of 660 miles in the other. Its age has relations with the eocene of Europe. Notwithstanding the order presented in various parts of this large region, the authors consider the various trap rocks as all younger than these beds, the lower having in fact been the younger. The trap, they hold to have flowed into and over and to have altered the lowest of these tertiary beds, which were deposited in a series of great lakes of no great depth.

Above the trap another series of beds occurs, the lowest of which is *laterite*, a well-known term to those who are conversant with Eastern Asiatic geology. In this, the authors state, occur the diamond mines east of Nagpur. They dispute the assertion that the diamonds belong to the transmuted sandstones below the trap; and say that at Weiragad (about 80 miles S.E. of Nagpur) there is no sandstone, but quartzose metamorphic rocks only. At that place the diamonds occur in a lateritic conglomerate, which overlies the sandstone in other places, and in which ferruginous cements occur formed from the detritus and boulders of adjoining formations; and this they hold to be the diamond conglomerate. It is therefore assumed to be younger than the overlying trap formation. Above comes in a series of deposits, the lowest of which is brown, the middle red, with existing fluviatile shells, land shells, and bones of mammalia (which Professor Owen has since determined to be those of buffalo and antelope); tusks of a large animal were also found in the brown clay. The uppermost deposit of all is the Regur or black cotton soil, in which kunkur is mixed. Bones of oxen and sheep are found in it.

Messrs. Hislop and Hunter consider these *black and red clay* beds to belong to the *post-pliocene* formations; the *brown clay* to the newer pliocene.

Assuming these Nagpur deposits to be correctly placed, diamonds of India are still, according to evidence collected from other authorities and already considered, traced to a conglomerate which may be more recent than our basalts on the Cudjengong, but may not be more recent than those at Ballarat; but which seems to have derived its pebbles and boulders from palaeozoic and metamorphic and ordinary igneous rocks; *laterite* itself covering rocks alike of every older epoch. Occurring as this detrital covering does all over India, and having the same relative position to all kinds of rocks, and at all heights up to that of at least 8000 feet above the sea, the idea of diamond belonging to it as its actual source is not sustainable.

In a subsequent paper (*Q. J. G. S.*, vol. xvi.) the Rev. S. Hislop, one of the authors, considers the intertrappean tertiary bed as lower eocene, producing good fossiliferous evidence for this opinion; and shows that the Mahadeva or Bangnapilly sandstone is about the same age, in which Dr. Oldham seems to coincide. (*"Memoirs of India,"* vol. i., p. 171.) Hislop's views have not been thoroughly received by other geologists; and doubts have been expressed as to whether the trap or basaltic formation of India is not all of one age.

If compared with the Cudjengong diamond deposits, the older of which, and from which the younger is derived, underlies the trap (basalt), it will be seen there is a difficulty to be reconciled with respect to each; and if the diamond conglomerate of India be lower eocene, that difficulty is complicated by assuming that the Cudjengong deposit is pliocene.

On reviewing the whole evidence I am inclined to believe that unless they are much younger than the

the pliocene or pleistocene epochs, in fact of recent origin, they must be considered as drifted from rocks older than the carboniferous. As they everywhere exist in limited areas, it would also be a fair inference that as there is no want of carbon, and similar agencies must operate over enormous regions, the limited range of diamond is a strong argument against its recent production. If the facts advanced by several of the authorities whom I have quoted are received, then diamond must have undergone processes similar to those that have resulted in the formation of gems, of which there is no dispute as to probable age.

It is remarkable how silent observers in general in India are as to the multiplicity of such gems and other extraneous minerals in the Indian diamond regions. Yet Mr. Carter names quartz, jasper, Lydian stone, epidote, mica-cous iron, garnets, and corundum, derived from rocks of different ages.

There is another interesting locality near Gungpur, on the northern frontier of Orissa, on a river running to the Bay of Bengal, north of Kuttak; but I have no accurate knowledge of its history.

To these remarks on Indian diamond beds I have only to add, that in 1867, I had the honour of a visit from an officer of the Bengal army, whose official position gave him great opportunities of acquaintance with the country, and who came to this colony on a tour of inspection, to examine our railways and coal-beds, and from him I learned that the Vindhyhan conglomerate is chiefly made up of jasper, chalcedony, specular iron, and a green rock, which latter lies *en masse* on granite; that the diamonds are of all colours—rose, yellow, brown, black, and *pale green*—which last being the favourite, or national colour of the followers of Mahomet, causes the green diamond to find a ready sale, whilst the others are neglected. In size they are that of a hazel nut, or larger. But, he added, that in the diamond districts the people are wretched; they think and talk of little but diamonds, which they often swallow if not watched.

(To be continued.)

ON THE ESTIMATION OF SULPHUR BY BARIUM.

By E. F. TESCHEMACHER and J. DENHAM SMITH.

(Concluded from p. 62.)

In each of the preceding experiments the *modus operandi* was the same; the precipitation being effected when both solutions were boiling, a dense arenaceous precipitate fell, which was most easily and quickly washed. Boiling water only was used for the first washings, so as to induce the solution of any adherent chloride of barium, then diluted and hot hydrochloric acid to remove any other possibly adherent salt, finally, boiling water only; the precipitate then was collected on a filter, and washed until the filtrate was not affected by a solution of silver. The precipitate was dried and then ignited on porcelain, first of all gently, and then to redness over a Bunsen burner, the filter-paper being burnt separately, and the weights added together in the usual mode. In every instance, the ignited sulphate was a pure white and soft powder, yielding both chlorine and barytes to water, and still more barytes when treated with diluted nitric acid.

In one instance only throughout the above experiments does the weight of the sulphate obtained fall below the calculated amount; in all the others it is above it, varying from about $\frac{1}{4}$ to more than 2 per cent in excess, and this when the perfect freedom of the ignited sulphate from the iron base is made evident by its whiteness. So it is clear, despite the especial pains taken to free the precipitate from any adherent salt, that, in eight out of the nine experiments, barium, in some form, has combined with the precipitated sulphate, and thus brought about an increase of weight, when, but for this, from the solubility of the

sulphate in hydrochloric acid, there ought to have been a deficiency.

Although, from experiments which preceded those just described, but which it will be more convenient to consider hereafter, as well as from long practice, we could safely rely on crystallised sulphate of iron as being of an uniform, constant, and definite composition, we thought it well to substitute another sulphate for it, so as to ascertain whether we should be equally at sea with it as with the ferrous sulphate. Accordingly, we fixed on crystallised sulphate of magnesia, which may readily be obtained pure and containing its exact amount of water of crystallisation, several determinations yielding 51·20 per cent of water, which is the calculated quantity. Of this salt, 96·10 grs. is equal to 12·50 grs. of sulphur, or 91 grs. of sulphate of barytes, and proceeding as above described, only replacing the iron by the magnesium salt, we obtained from 96·10 grs. of sulphate of magnesia—

No. 1.	93·00 grs. of sulphate of barytes.
" 2.	92·15 " " "
" 3.	92·60 " " "

and in each case the ignited sulphate yielded chlorine, magnesia, and barytes to water and to acid. It was obviously useless to multiply these experiments, as, although the range of difference is not so great as with the iron salt, yet the weight of sulphate is always in excess, and this sufficiently marked as to confirm us in distrusting the estimation of sulphur by barium.

Our next step in this investigation was to determine the weight of sulphate of barytes yielded by 108·60 grs. of crystallised sulphate of iron after oxidation, as in the estimation of sulphur in pyrites, in other respects following the process already described.

No. 1.	89·70 grs. of sulphate of barytes.
" 2.	87·05 " " "
" 3.	90·10 " " "
" 4.	89·70 " " "
" 5.	89·40 " " "
" 6.	88·90 " " "
" 7.	90·80 " " "
" 8.	91·00 " " "
" 9.	90·00 " " "

Here the reverse of the preceding experiments obtains; in no case is there an excess of weight of the precipitate—in one instance only does it amount to the calculated weight which, in the other eight examinations, is never attained; indeed, this loss is so constant, yet so variable in amount, as to prove that the gravimetric method of estimating the sulphur in pyrites must be abandoned. This loss is the more worthy of remark from the discolouration, in every instance, of the precipitate by oxide of iron, the colour varying from buff to a deep salmon tint; and, also, which seems to be invariable, the presence of chlorine and barytes soluble in water and acid in all the precipitates, so that the actual loss of sulphate is, in every case, even greater than the apparent loss.

This would have been more evident had we not thrown away the filtrates and washings of the first six of the preceding experiments before we bethought ourselves that it was desirable to ascertain whether any sulphate of barytes was held in solution; however, on mixing the filtrates and washings of the three last, and evaporating, we obtained 4·20 grs. of sulphate of barytes, which, added to the precipitates, and averaged, shows the adherent salt to have amounted to 1 gr. in each instance, and to a loss of 1·40 grs. of sulphate of barytes in each experiment. He must especially dwell on this customary deficiency of sulphate of barytes when precipitated from an acidified solution of a soluble sulphate as casting the gravest doubts on the trustworthiness of all analytic results thus obtained, and even leading to but widening error, when the resultant sulphate has been purified from its adherent salts by subsequent treatment with dilute acids.

As our aim in these remarks is, not only to prove the futility of relying on the ordinary methods of estimating sulphur by barytes, but especially their worthlessness as applied to pyrites, we followed the foregoing experiments with three more in duplicate, on a sample of pyrites which we have already ascertained contained 49 per cent of sulphur. 25 grs. of this pyrites, which ought to yield 89·20 grs. of sulphate of barytes, oxidised in the usual manner, but the solution not evaporated to dryness, and, therefore, containing some nitric acid, yielded 90·10 grs. of sulphate of barytes, when the filtered solution and washings were precipitated, by 120 grs. of crystallised chloride of barium, from the boiling solution, this left to cool, and the resulting sulphate washed with diluted and hot hydrochloric acid, and then with hot water till free from chlorine. This 90·10 grs. of sulphate of barytes indicates 49·50 per cent of sulphur. The filtrate and washings of this precipitate yielded 1·10 grs. of sulphate of barytes when evaporated, which, added to the weight of the precipitate, indicates just over 50 per cent of sulphur in this sample of pyrites, or an error in excess of 1 per cent of sulphur. Of the 90·10 grs. of this ignited precipitate, 80 grs., when boiled with diluted hydrochloric acid, washed, collected, and ignited, yielded 78·40 = 88·30 grs. on the whole amount, indicating 48·50 per cent of sulphur. This experiment exactly repeated, yielded 90·50 grs. of sulphate = 49·70 per cent sulphur. Filtrate and washings gave 1·05 grs., which, added to the above, indicates 50½ per cent of sulphur. Of the ignited precipitate, 80 grs. when purified left 78·20 grs. = 88 grs. on the whole amount, or rather less than 48½ per cent of sulphur.

Another 25 grs. of pyrites were oxidised, and the solution evaporated to expel nitric acid, then re-dissolved in about 200 grs. of hydrochloric acid, and solution and washings treated as in the foregoing experiments. The ignited sulphate weighed 88·80 grs. = 48·78 per cent of sulphur. The filtrate &c., in this instance left 0·70 gr. of sulphate; and 80 grs. of the ignited precipitate, treated as above with dilute acid, left 78·50 = 87·15 grs. on the whole amount, or 47·87 per cent of sulphur. This experiment also exactly repeated gave 87·30 grs. sulphate = 47·88 sulphur. 80 grs. ignited sulphate when purified left 78 = 85·10 grs. sulphate on the whole, or 46·75 per cent of sulphur. Filtrate and washings left 1·50 grs. sulphate of barytes.

Again, 25 grs. of this pyrites, oxidised, evaporated, and re-dissolved in 700 grs. of hydrochloric acid, and then proceeding as above, only washing the precipitate with but slightly diluted acid in the first instance, yielded 88·80 grs. of ignited sulphate = 48·78 per cent of sulphur: and 80 grs. when purified left 77·90 or 86·50 grs. on the whole amount = 47·50 per cent of sulphur. Filtrate, &c., left 1·60 grs. of sulphate of barytes. This experiment also when exactly repeated gave 89·35 grs. of ignited sulphate = 49·10 per cent sulphur. This, purified, yielded 87·35 grs. on the whole amount, or 48 per cent of sulphur, filtrate and washings being equal to 1·60 grs. of sulphate.

Let us tabulate the final results in sulphur of these experiments—column A indicating the percentage of sulphur calculated from the original precipitate. Column B, this, plus the deposit yielded by the filtrate and washings, and C the percentage of sulphur on the assumed purified precipitates.

A.	B.	C.	
49·50	50·00	48·50	per cent of sulphur.
49·70	50·30	48·45	
48·78	49·16	47·87	"
47·88	48·78	46·75	
48·78	49·66	47·50	"
49·10	50·00	48·00	

Columns A and B are often near to the truth, or 49 per cent of sulphur; the error from the solubility of the sulphate being nearly or more than compensated by adherent impurity; but when the sulphate is subjected to subsequent treatment as in column C, the wide departure

of the results from the truth, and consequent invariable deficiency and error by loss of sulphur, is manifest. Indeed, as we have shown before, this purifying process is unending, all these purified precipitates again yielding barytes on treatment with diluted acids.

We think those readers who have followed us thus far will admit that we have proved the estimation of sulphur and sulphuric acid by the weight of the sulphate of barytes obtained is, and can be, correct only by accident, and when the adherent impurity happens exactly to counterbalance the sulphate dissolved. That sulphate of barytes, when precipitated from a solution by an excess of a soluble barytic salt, invariably takes down with it some of the precipitant, and often salts of other bases which may be present in the solution, and thus vitiates the results. That sulphate of barytes, when ignited over a gas-flame, is always reduced to a noticeable extent. That if it be attempted to purify such sulphate from the adherent salts, that the results are always and still further erroneously affected, and that sulphate of barytes is notably soluble in water acidified by hydrochloric acid, and this to an extent sufficient to falsify all results.

Although the foregoing series of experiments are recent, the facts they point to have long been known to us, and have gradually led to a method of estimating sulphur by barium, more especially the sulphur in pyrites, which experience and continuous use have proved to us to be exact, reliable, and to yield constant results. This method we shall now, in concluding these remarks, endeavour to describe in detail, requesting the patient attention and consideration of our readers for the difficulty we feel in conveying a lucid description of a process which necessarily involves some practice and judgment on the part of the operator to ensure both rapidity in working and correctness of results, although these are assured when once the practical details of the method are mastered.

This method is based on five conditions, viz.—

- The use of a standard solution of chloride of barium, *by weight*.
- The complete oxidation of the sulphur, and subsequent expulsion of all the nitric acid.
- The avoidance of a large excess of hydrochloric acid in the solution.
- The avoidance of large quantities of solutions.
- The use of considerable weights of pyrites in testing, thus avoiding the extreme of multiplication of any analytical error in the percentage return.

The preparation of the standard solution of chloride of barium, now that this salt is met with in commerce so pure and definite in composition, offers no difficulty and requires no details from us, excepting that we find it convenient in practice and for the sake of the ready calculation of results that *1000 grs. by weight* of this solution shall be equal to and represent *25 grs. of sulphur*. It is advisable to use water just acidified with hydrochloric acid in making this solution, to prevent the deposition of carbonate of barytes, which often occurs when the standard solution is kept.

To prove the correctness of this standard solution it is not enough to precipitate known weights, collect, and weigh the resulting sulphate, as these results slightly vary, but it is advisable thus to check the solution as a confirmatory measure by repeated tests, adding, say, 1000 weighed grs. of the standard solution, heated nearly to boiling, to a boiling solution of diluted sulphuric acid containing an excess of acid, when the sulphate of barytes obtained yields traces only of chlorine to water after ignition; but if this order be reversed, and the diluted sulphuric acid is added to the solution of chloride of barium, so that this latter is in excess, until complete precipitation is effected, then the sulphate of barytes will be found to yield abundant evidences of chloride of barium when treated with water after ignition. In any way of testing this standard solution the results will, however, closely approxi-

mate to the truth, since in seven tests of the standard solution 1000 grs. yielded 181.40 grs. as the lowest, and 182.30 grs. as the highest weight of ignited sulphate, whilst 181.95 grs. is the average of these seven tests, the calculated weight being 182 grains. This average exactness is in great measure due to the insolubility of sulphate of barytes, in a solution wherein free sulphuric acid is present. Although the error of this test, either way, is but slight, still it is error; so that it is advisable to rely on the crystallised sulphate of iron already described as the ultimate and final test of the accuracy of the standard solution of chloride of barium. Thus, 108.60 grains of this salt = 12.50 grs. of sulphur, is dissolved in about 1000 grs. of water slightly acidified with hydrochloric acid, and heated nearly to boiling; to this is added standard solution of chloride of barium somewhat below the estimated weight, say, 490 to 495 grs., also heated, stirring all the time, and then boiling rapidly. A small portion of the solution is then filtered and the standard solution added, drop by drop, to the filtrate, which must be returned to the test liquor and boiled at each testing until a filtrate is obtained, which, after standing, just clouds both with dilute sulphuric acid and the standard barium solution. In practice it will be found that a standard solution is readily obtained, 500 grs. of which treated as above with 108.60 grs. of crystallised sulphate of iron will yield a filtrate manifesting slight cloudiness both with barytes and sulphuric acid, and which with a deficiency of 2 grs. in the test of the standard solution will yield a marked precipitate on the addition of the 2 grs. to the filtrate, and an equally well-defined reaction with dilute sulphuric acid when 2 grs. in excess of the standard solution of barium has been used. The operator will naturally make sufficient standard solution for some six or twelve months' consumption; but this should not be tested and rectified until it has been made for some forty-eight hours, and then no pains must be spared to ensure its accuracy and exact adjustment. Thus, in addition to the weight of sulphate spoken of above, the average of which was 181.95 grs., the estimated weight being 182 grs., we find the required weight of our standard solution of chloride of barium, when controlled and verified by the already-named weights of crystallised sulphates of iron and of magnesia, equivalent to 12.50 grs. of sulphur, in eleven consecutive tests to be 501, 501, 500, 501, 500, 499, 499, 500, 500, and 500 grs. and with such testing we are satisfied of the reliability of the standard solution, and rest content; merely taking the precaution to re-test from time to time, as when opening a fresh Winchester quart, so as to prevent mistakes of any kind creeping in.

We may be forgiven for insisting at such lengths on ensuring the rigid accuracy of the standard solution of barium, as this is essential to correctness of results; and we now turn to the Estimation of Sulphur in Pyrites. When the sample to be tested occurs in lumps, the whole must be broken down and passed through a sieve of about 120 meshes to the square inch, then thoroughly mixed, turned out on paper, and spread out to a uniform but shallow depth, portions being now taken from various parts with a scoop or laboratory knife, returned to a hard porcelain mortar, and ground still finer. From this another portion is taken in a similar manner and again ground in the usual way. Of this from 100 to 200 grs. are again taken, and ground as finely as possible, and then dried on a water-bath at 212° F. It is essential, and this most especially with the poorer crystalline ores, that this test-sample be reduced to an impalpable powder. Of this test-sample, carefully but rapidly dried, let two portions of 25 and 30 grs. each be weighed and placed in separate flasks with long necks, and of from 16 to 20 ozs. capacity; the flasks being previously damped inside with a few drops of distilled water so as just to moisten the pyrites, and then loosely closed by placing small funnels in their mouths. A mixture of some 50 grs. of hydrochloric acid and 150 of nitric acid, sp. gr. 1.40, by measure, is then to be poured into each flask, but not directly upon the ore, and immediately a quick rotary motion given to the flask, so as to rapidly mix the ore and

acid, which may and ought to be effected and the flask placed on a ring in an oblique position, before action takes place. Action rapidly and energetically ensues, and so soon as it ceases, add 200 grs. of additional hydrochloric acid, place the flask on sand or hot plate for evaporation, which is to be carried *just* to dryness, a point which demands care and watchfulness to hit; 100 grs. more hydrochloric acid is then added to the flask to re-dissolve the contents. Now is the time to detect whether the oxidation of the sulphur is complete or no, as the merest trace of free sulphur may be recognised in the flask by the eye; and, if so, then reject the experiment and begin *denovo* on fresh portions of the test-sample still more thoroughly ground.

A small flask holding some 1000 grms. of standard solution of chloride of barium, with dropping tube, is now counterpoised, and so much of the solution transferred to a porcelain basin as practice shows may be looked for as nearly equivalent to the strength of the pyrites in sulphur.

The requisite quantity of standard solution is a point which must be left to the experience and judgment of the operator; thus, with the best Spanish ores we start with 480 to 485 grs. of standard solution to the 25 of pyrites; with other amorphous ore, 450 grs. is an average amount; whilst with crystalline pyrites 350 to 410 grs. of standard solution is sufficient to start with. Whatever the amount may be, it is to be heated nearly to boiling and poured into the test-solution of the pyrites, having previously washed the neck of the flask and funnel with hot water to carry down any adherent splashes; then the whole returned to the basin from the flask, which must be repeatedly washed with small quantities of water and added to the solution in the basin, taking care that the whole of the solutions and washings shall not exceed in bulk 1500 measured grs. of water. Now boil rapidly, and having a small damped filter ready, filter a little of the mixed solution, and add a portion of the filtrate to about 3 or 4 grs. of standard barium solution placed, from the counterpoised flask containing it, in a test-glass. Should a further precipitate be produced, this tested solution is to be returned to the basin with the rest of the filtrate, and so much more standard solution of barium added as in the judgment of the operator is required, this is again boiled and filtered, using the same filter, and tested as before, repeating this operation until a precipitate ceases to appear with the standard barium solution, when the weight of the solution employed is to be taken and noted. When this point is arrived at, a portion, some 3 or 4 grs., of a standard dilute sulphuric acid, which it is convenient to have equivalent to the standard solution of barium, weight for weight, is to be placed in another test-glass, and a little of the filtrate poured upon it. Should this not yield a precipitate, or should both barytes and sulphuric acid show a cloudiness only on standing for a few minutes, the operation may be pronounced complete, and the test confirmed by proceeding with the second test-solution of the pyrites as above, but adding at once the exact and ascertained weight of the standard barium solution. Should this, also, on testing, confirm the first test, and the filtrate yield evidence neither of barytes nor sulphuric acid, we regard the estimation as complete; the amount of sulphur being easily calculated from, and confirmed by, the weights of standard solution of chloride of barium employed, which should agree within 1-500th, or the operator have recourse to a third test or more, until he is satisfied of his correctness.

When too much chloride of barium solution has been added in the first instance, and consequently a precipitate obtained with standard sulphuric acid, the filtrate is returned to the basin, and boiled with gradual additions of the standard sulphuric acid until the point is attained when neither barytes nor sulphuric acid causes a precipitate, so that the chloride of barium in excess may be deducted from the weight used in the first instance; but it is well to test the pyrites under examination a third time, and to employ the result of this first test as a guide only to the actual test

and re-test on which the operator intends to rely when he has overshot the mark and added an excess of standard barium solution in the first instance. We must be allowed to recommend that in all cases when the operation approaches completion, the filtrate, after the addition of barium solution or sulphuric acid, should be allowed an interval of two minutes before testing it the reverse way.

Estimated by the method we have thus endeavoured to describe, the amount of sulphur in pyrites may be determined with accuracy and certainty to a 1000th part or 1-10th per cent; and the sulphuric acid present in any solution may thus be estimated with ease, taking care to avoid too great dilution of the sulphate.

It may be as well to add, that 108.60 grs. of sulphate of iron = 12.50 sulphur, oxidised as in the above-described method, required, in five consecutive experiments, 500 and 501 grs. by weight of the standard barium solution, the filtrate either remaining transparent or slightly clouding with both barium and sulphuric acid; thus proving that no loss of sulphur is sustained by oxidation. It is seldom the difference between the original and confirmatory test of a sample of pyrites exceeds 0.10 per cent, whilst they usually agree. Also, that the crystalline pyrites, of which the Norwegian ore is a type, is apt to deposit free sulphur during oxidation, unless most carefully ground; so that, with such ore, this point must be more carefully looked to than when amorphous samples, like most Spanish ores, are valued.

We have now only to state that, whilst the mode we have endeavoured thus to bring into notice is far more rapid than the gravimetric method of estimating sulphur, the results are so constant and reliable that, should it meet with general adoption and use by those interested in the subject, we feel assured the differences in estimating the value of pyrites, and consequent disputes which have caused so much annoyance to ourselves and others, will cease to exist.

NOTE.—Dr. Noad has obligingly called our attention to his comments upon some observations of Mr. Calvert, "On the Solubility of Sulphate of Baryta in Acid Liquors;" wherein that author says, "The insolubility of this salt is affected even by the weakest nitric or hydrochloric acids, and that in future the practice of rendering liquors acid with either of these acids must be discontinued when sulphates are to be determined." Dr. Noad, in this paper, which may be found in the *Quarterly Journal of the Chemical Society*, vol. ix., p. 15, most strongly insists on the fact, that sulphuric acid may exist in the nitric acid of commerce without the production of a precipitate on the addition of a soluble salt of barytes; thus furnishing another probable source of error in estimating the amount of sulphur present in pyrites.

As we read the remarks of Dr. Noad, we find our observations on the solubility of sulphate of barytes in solutions acidified by hydrochloric acid fully confirmed by his experiments; and that "the solubility of sulphate of baryta in a large bulk of dilute hydrochloric acid" has been conclusively proved by himself and confirmed by us, although we must beg leave to differ from him in his conclusion, "that in a practical point of view it is of no importance," as, so far as our experience goes, whether the hydrochloric acid used be strong or dilute, sulphate of barytes is always dissolved in the acid solution; and that a considerable excess of the soluble barytic salt only tends in some measure to counterbalance the loss sustained by solution of the sulphate, by its adhesion to the precipitated sulphate of barytes, forming therewith a compound insoluble both in water and dilute acids. And, consequently, we re-affirm, "that we have proved the estimation of sulphur and sulphuric acid by the weight of the sulphate of barytes obtained is, and can be, correct only by accident, and when the adherent impurity happens exactly to counterbalance the sulphate dissolved."

NOTICES OF BOOKS.

The Retrospect of Medicine: Being a Half-Yearly Journal containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by W. BRAITHWAITE, M.D., and JAMES BRAITHWAITE, M.D. Lond. Vol. lxiii., January—June, 1871. London: Simpkin, Marshall, and Co. Edinburgh: Oliver and Boyd. Dublin: Hodges, Foster, and Co.

THE advent of these well-known volumes edited by Drs. Braithwaite must be welcome to the hard-worked medical man who has little time to read up in cases not immediately presented to him. The volume for the past half-year fully continues the high character of those already issued.

Among the many valuable papers that "On a Rapid and Accurate Method of Milk Analysis; with a special reference to the Examination of Woman's Milk," by Dr. Muter, the Director of the South London School of Chemistry and Pharmacy, is by no means the least interesting. He says:—"After many trials in various directions, it was determined to base the analysis on the real dietetic value of the milk, as represented by a determination of its solid residue and the estimation of its nitrogenous and carbonaceous constituents. Experience derived from the use of Dr. Frankland's elegant system of water analysis by combustion *in vacuo* led ultimately to the application of a similar principle to milk. The process, when used for cow's milk, requires several modifications, in view of possible admixture with certain extraneous matters. The process is conducted as follows:—A small paper filter is prepared which will contain 10 grms. of oxide of copper. It is filled with the oxide and placed in a small funnel. The whole is then exposed for an hour in an air-bath, so constructed as to draw a continuous current of air at 105° C. through and around the funnel. The funnel and its contents are then cooled in the desiccator, and weighed with great care, and the weight having been noted, *five drops* of the milk are cautiously let fall on the centre of the oxide, taking care that no milk spreads to the filter paper. The whole arrangement is then weighed, and the quantity of milk used found by difference. The funnel and contents are then replaced in the air-bath, and exposed to a temperature gradually increasing from 50° to 105° during several hours. When the milk has been thus dried it is again weighed at intervals until it ceases to lose weight. This loss of course shows the percentage of water, and, consequently, of the total solids. The contents of the filter are now transformed to a warm glass mortar, mixed with more oxide of copper and introduced into a combustion-tube. The tube is charged in the usual way, but the front part is filled through 3½ inches of its length with a roll of copper gauze previously ignited in hydrogen. The end of the combustion-tube is then drawn out before the blowpipe, and connected by an india-rubber and glycerine joint to the Sprengel air-pump. Heat is now applied to the front part of the tube, and, the air having been fully exhausted, the combustion is proceeded with, and the residual gases received into a tube over mercury. At the close of the combustion the gases are entirely transferred from the combustion to the receiving tube by the aid of the pump, and it now only remains to measure them in a manometric apparatus. The gases are first measured as a whole, and then separately absorbed by the usual reagents and measured after each absorption. We thus obtain the total volumes of carbon dioxide and nitrogen evolved by the milk-residue, and by a simple set of calculations we are enabled to deduce the actual weight of carbon and nitrogen contained in it, and consequently its exact value in nutriment. In one continued series of operations we therefore ascertain (1) the total solids, and (2) the amount of their flesh-forming and heat-producing constituents. When thus complete, the analysis would be expressed as follows:—

Amount of milk taken, 0.24 grms.	
Total solids, 0.0264 = 11 per cent.	
Organic nitrogen 0.0014 = 0.5833 per cent.	
" carbon 0.0167 = 6.5420 "	

Therefore—

Water	89.00
Flesh-formers (casein)	3.71
Heat-producers (fat and sugar) ..	7.29
	100.00

This is a good specimen of well-balanced healthy milk."

The clinical value of such a plan of analysis it would be difficult to over-estimate, especially as the quantity of milk required is so small as to be easily procurable at any time.

There is another very interesting extract on a Method of Embalming the Dead. Embalming seems in many cases desirable, not only as a sanitary precaution in large towns, where, as in Edinburgh and Glasgow, the dead are placed in family vaults situated in the very heart of the city, but as being of service to the anatomist, and enabling those whose relatives have died away from home to procure the body in a state presenting hardly any post-mortem change. Dr. Vivodtseff's process is simple, short, and easy of accomplishment, consisting merely in the injection of a mixture of carbolic acid and alcohol into the arteries by means of Dr. Richardson's apparatus for local anæsthesia, the quantity of the mixed fluid equalling about one-half the weight of the body. But these papers are not of exceptional interest, and very lengthy extracts would have to be made to do justice to the editors' happy compilation.

CORRESPONDENCE.

RING VORTICES.

To the Editor of the Chemical News.

SIR,—In the *Philosophical Magazine* for 1864 will be found two papers by Mr. Charles Tomlinson, on figures of this kind, which he calls "submergence cohesion figures." His experiments are exceedingly numerous and interesting, well worth study, and relate mainly to oils. He gives his

Section of Head of Smith's Cold Chisel, showing how rings of metal may be made.

views of the causes of the formation of these rings in these words:—"Take the case of a liquid ring. The forces are (1) *diffusion*, which forms the ring; (2) *gravity*, which causes it to sink. The resistance is *friction*, retarding (1) the descent of the ring, (2) its diffusion."

It will be seen I differ from Mr. Tomlinson as to the causes, and especially as to the correlation, of these phenomena. I think the "ring" is due to the ordinary motion following from the impact of two bodies, just as the smith's chisel head is "burred" out and recurred by

blows, showing the commencement of a cold metal "ring." The descent is due mainly to the initial velocity of the drop, and although diffusion may modify, and so, in one sense, may be said to create these phenomena, yet it really is the cause of their destruction. Finally, I think the ordinary laws of motion applied to streams of fluids impacting on other matter is sufficient to account for nearly all the phenomena. Least of all, I think, is the effect of cohesion on such "rings" as I am considering, viz., those formed in similar fluids by one small portion moving at greater velocity than another, i.e., by impact. This is clearly shown also, I think, by the influence exerted on these phenomena by the area of the receiving vessel.—I am, &c.,

HENRY DEACON.

Edinburgh, August 5, 1871.

MISCELLANEOUS.

British Association for the Advancement of Science.

—The following is a complete list of the papers which were brought before Section B (Chemical Science) at the Edinburgh Meeting, under the presidency of Dr. Andrews, F.R.S., &c. They will be published, in full or in abstract, according to their importance, in the CHEMICAL NEWS:—
The President's Address.

J. Dewar.—*Preliminary Report on Thermal Equivalents of the Oxides of Chlorine.*

J. H. Gladstone and Alfred Tribe.—*Some Experiments on Chemical Dynamics.*

Charles Tomlinson.—*On the Behaviour of Supersaturated Solutions when Exposed to the Open Air.*

Thomas Ainsworth.—*Facts developed by the Working of of Hamatite Ores in the Ulverstone and Whitehaven Districts from 1844 to 1871.*

C. Gilbert Wheeler.—*Recent Progress in Chemistry in the United States.*

Henry Deacon, J.P.—*Deacon's Chlorine Process as applied to the Manufacture of Bleaching Powder on the larger scale.*

T. L. Phipson, Ph.D.—*On Regianic Acid.*

Dr. Crace Calvert.—*On the Estimation of Sulphur in Coal and Coke.*

E. C. C. Stanford.—*On the Retention of Organic Nitrogen by Charcoal.*

J. Smyth.—*Improvements in Chlorimetry.*

W. Delffs.—*On Sorbit.*

Emerson Reynolds.—*On the Action of Aldehyde on Sulpho- and Oxygen-Ureas.*

Emerson Reynolds.—*On the Analysis of a Singular Deposit from Well-Water.*

W. Chandler Roberts.—*The Molecular Arrangement of the Alloy employed for the British Silver Coinage.*

T. Moffat.—*On Ozonimetry.*

Dr. Andrews.—*On the Dichroism of the Vapour of Iodine.*

Dr. Andrews.—*On the Action of Heat on Bromine.*

Dr. O. Richter.—*On the Chemical Constitution of Glycolic Alcohol and its Heterologues, as viewed in the new light of the "Tyro-Nucleus" Theory.*

Report of the Committee on the Utilisation of Sewage.

Dr. Bischof.—*On the Examination of Water for Sanitary Purposes.*

Mr. Weldon.—*On a Proposed Method of Recovering the Sulphur Employed in the Manufacture of Soda.*

Abbé Moigno.—*On the Photographic Post.*

Dr. Thorpe.—*Contribution to the History of the Phosphorus Chlorides.*

Mr. Pattison Muir.—*On an Antimony Ore from New Zealand.*

Mr. John Dalzell.—*On Sulphur Dichloride.*

Dr. Wright.—*On the Oxidation Products of the Essential Oil of Orange-Peel.*

Dr. Wright.—*On some New Derivatives from Codcia.*

Dr. Delffs.—*On a Modified Method of Testing for Morphine.*

Mr. Tichborne.—*On the Dissociation of Molecules by Heat*

Mr. J. Y. Buchanan.—*On the Rate of Action of Caustic Soda on a Watery Solution of Chloroacetic Acid.*

Mr. Hope.—*Experiments on Britton's Farm.*

Dr. Corfield.—*Comparison of Results during Winter of Croydon, Norwood, and Britton's Farm Experiments.*

Dr. Corfield.—*Report on Analysis in connection with above.*

Dr. Corfield.—*Upward Filtration of Sewage at Ely.*

Dr. Corfield.—*Phosphate Process.*

Drs. Corfield and Gilbert.—*Dry-Earth. System at Lancaster.*

Report of the Committee appointed for the purpose of Superintending the Publication of Abstracts of Chemical Papers.

Prof. Apjohn.—*Some Remarks upon the Proximate Analysis of Saccharine Matters.*

Dr. Gladstone.—*On Crystals of Silver.*

Mr. Braham.—*On the Crystallisation of Metals by Electricity.*

Mr. J. S. Holden.—*On the Aluminous Iron Ores of County Antrim: their History and Composition.*

Prof. Maskelyne.—*On Dufrenite and a New Mineral from Cornwall.*

Prof. Maskelyne.—*On Localities of Diopase.*

Dr. Goodman.—*Note on Fibrin.*

Rev. H. Highton.—*On a Method of Preserving Food by Muric Acid.*

Mr. Wanklyn.—*On the Constitution of Salts.*

Mr. Harkness.—*Preliminary Notice on a New Method of Testing Samples of Wood-Naphtha.*

OFFICERS AND COMMITTEE.

President.—Prof. T. Andrews, F.R.S. L. and E.

Vice-Presidents.—Prof. Abel, F.R.S.; Prof. Apjohn, F.R.S.; Prof. Crum Brown, F.R.S.E.; Dr. Ronalds, F.R.S.E.; Prof. H. E. Roscoe, F.R.S.; Dr. J. Stenhouse, F.R.S.; Prof. A. W. Williamson, F.R.S.; James Young, F.R.S.E.

Secretaries.—J. Y. Buchanan, F.R.S.E.; W. N. Hartley; T. E. Thorpe, F.R.S.E.

Committee.—J. Attfield; Dr. Baumhauer; G. Bischoff; J. C. Brown; Crace Calvert, F.R.S.; M. Carteighe; R. C. Clapham; W. Crookes, F.R.S.; H. Deacon; R. E. Delffs; James Dewar, F.R.S.E.; Dr. Baker Edwards; A. E. Fletcher; R. Gerstl; J. H. Gilbert, F.R.S.; J. H. Gladstone, F.R.S.; W. Harkness; W. E. Heathfield, F.R.S.E.; J. Hunter; Dr. Jennings; J. Kraft; Dr. Longstaff; Stevenson Macadam, F.R.S.E.; Abbé Moigno; Prof. Maskelyne; R. C. Moffat; E. C. Nicholson, F.R.S.; B. H. Paul; W. H. Perkin, F.R.S.; J. A. Phillips; Lyon Playfair, C.E., M.P.; Astley Price; J. E. Reynolds; T. H. Rowney; Angus Smith, F.R.S.; J. Smyth, jun.; E. C. C. Stanford; W. W. Stoddart; J. M. Thomson; C. R. C. Tichborne; C. Tomlinson, F.R.S.; A. Tribe; W. Weldon; Prof. Stephen Williams; W. Williams; C. R. A. Wright, D.Sc.

University of London.—The following are lists of the candidates who have passed the recent First B.Sc. Examination.—*Pass Examination.* (First Division).—Robert William Atkinson, University College, and Royal School of Mines; Frederick Douglas Brown, Royal College of Chemistry and private study; Thomas Carnelley, Owen's College; Robert Moses Lewis, B.A., Downing College, Cambridge; Hugh William McCann, Liverpool Institute; John Henry Poynting, Owen's College; James Richmond, Manchester Grammar School; Thomas Hutchinson Waller, B.A., private study. (Second Division).—Charles Callaway, M.A., Cheshunt College; Baron Armand De Watteville, M.A., University College; Charles William Huson, Queen's College, Liverpool; Alexander Irving, B.A., private study; Leander Starr Jameson, University College; Charles Coleman Jewell, University College; George Lewis, B.A., King's College and private study; Martin Stewart, Queen's College, Birmingham; John Foster Trafford, University College.

Quekett Microscopical Club.—The sixth annual meeting of this club was held on Friday evening, July 28th, at University College. By the annual report of the Committee read, it appears that the number of members now amounts to 550. The President, Dr. L. S. Beale, gave the annual presidential address. At the election of officers which followed, Dr. L. S. Beale was elected President for the year 1871-72; for Vice-Presidents, Dr. Robert Braithwaite, F.R.M.S., F.L.S., Mr. Arthur E. Durham, F.R.C.S., Mr. Charles J. Leaf, F.R.M.S., Mr. Henry Lee, F.Z.S.; for four Members of Committee, Messrs. W. H. Golding, T. Greenish, E. Marks, and F. Oxley; for Treasurer, Mr. Robert Hardwicke, F.L.S.; Hon. Secretary for Foreign Correspondence, Mr. M. C. Cooke, M.A.; Hon. Secretary, Mr. T. Charters White, M.R.C.S. The meeting then terminated in the usual *conversazione*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 12, 1871.

This number contains the following original papers and memoirs:—

Disulphobenzoic Acid and a New Dioxibenzoic Acid.—L. Barth and C. Senhofer.—Benzoic acid, having been placed along with anhydrous phosphoric acid and strong sulphuric acid, into a sealed tube, and heated to 250°, has yielded disulphobenzoic acid—

This body is very hygroscopic, and retains some water even at 130°. The salts of this acid are crystalline substances. When the potassa salt is fused with excess of caustic potassa, and the fused mass treated, after cooling and acidulating, with ether, the latter takes up a new acid, to which the authors give the name of dioxibenzoic acid. This substance crystallises in prismatic shape, and is characterised by not yielding (as protocatechutic acid, which is isomeric with this new acid, does) a green colouration with chloride of iron, and not being precipitated by acetate of lead. The dioxibenzoic acid fuses at 220°, but is partially decomposed at that temperature; its formula, in the air-dry state, is—

At 105°, this acid loses its water of crystallisation; heated with strong sulphuric acid, it is converted into a red-coloured fluid, which, by the addition of water, yields a green-coloured precipitate. The salts of this dioxibenzoic acid are crystalline substances. On being submitted to dry distillation, this acid does not yield any of the well-known bihydroxy-benzols. The authors are engaged with further experiments on the nature of the substances formed by the operation alluded to, and also with researches on the nature of the substance produced by the action of sulphuric acid.

Preparation of Protocatechutic Acid from Oxymybenzoic Acid, and on the Constitution of the first-named Acid.—L. Barth.—The gist of the contents of this paper is the communication of some experiments made by the author to prove that, notwithstanding the observations of Fittig and others, he duly obtained, from oxymybenzoic acid, protocatechutic acid, not due to the presence of any para-oxymybenzoic acid among the oxymybenzoic acid operated upon. When the position (Stellung) of para-oxymybenzoic acid is assumed to be 1-4, and that of oxymybenzoic acid 1-3, the position of protocatechutic acid should be 1-3-4.

Bimethyl- and Biethyl-Protocatechutic Acid.—R. Koelle.—Bimethyl-protocatechutic acid is prepared by putting into a tube (to be afterwards sealed) 1 gm. of protocatechutic acid, 4 grms. of iodide of methyl, and 1 gm. of pure caustic potassa dissolved in methyl-alcohol (not methylated spirits of wine). This mixture is heated in the sealed tube for some hours to 140°. The contents of the tube are first filtered, the filtrate next evaporated upon the water-bath, and the oily residue boiled for some time with dilute caustic soda solution. The liquid is next treated with dilute sulphuric acid, so as to acidify the fluid, from which then a flocculent substance—viz., the bimethyl-protocatechutic—is separated. This body, having been purified by

means of ether, exhibits a crystalline needle-shaped structure; formula—

point of fusion, 170°—171°. By distillation with lime, this substance which exhibits the very characteristic reaction with iron in the same manner as protocatechutic, yields an oily fluid boiling between 210° and 220°, and exhibiting a vanilla-like smell; the formula of this oil is—

Biethyl-protocatechutic acid is a solid substance, exhibiting a crystalline needle-shaped form, contains no water of crystallisation, and fuses at 149°; formula—

This acid yields also, when distilled with lime, a fluid similar to that just alluded to, and the potassa, baryta, and silver salts of both the acids hereinbefore mentioned are crystalline substances.

Contribution to the Theory of Dissociation.—A. Horstmann.—An algebraico-physical essay.

Contribution to our knowledge on the Combination Value (Verbindungswerthe) of the Elements.—C. W. Blomstrand.—Notwithstanding the high scientific value of this essay, it is, in consequence of its length and the large number of formulæ required for the proper understanding of this subject, not well suited for abstraction.

Synthesis of Oxaluric Acid.—L. Henry.—The author states that, by causing ethyl-oxy-oxalyl-chloride—

to act upon urea, oxaluric acid is produced according to the following formula:—

The result of this reaction is the production of oxalurate of ethyl—

which is soluble in boiling water, separates therefrom on cooling in crystalline state. This substance is difficultly soluble in alcohol, insoluble in ether, barely soluble in cold, but better in boiling water, and very readily dissolved by acids, alkalies, and ammonia. Heated to between 160° and 170°, this body fuses and becomes decomposed, yielding oxamethan, which volatilises and leaves cyanuric acid. Oxalurate of ethyl is decomposed by boiling along with water, oxaluric acid being probably thereby formed, because, when the oxalurate of ethyl is re-crystallised from boiling water, it leaves a mother-liquor which exhibits an acid reaction.

Experiments made with the view to ascertain the Time Required for the Volatilisation and Re-Condensation of Solid Bodies.—A. Naumann.—The bodies experimented with *in vacuo* were sesquichloride of carbon, C_2Cl_6 , which fuses under atmospheric pressure at 160°, and boils at 182°; and naphthalene, C_{10}H_8 , which, under the same condition, fuses at 79.2° and boils at 218°. The main result arrived at is, that the time required for the volatilisation and re-condensation of the substances operated upon is very short, and hardly longer than the time required to obtain the temperature corresponding to a certain pressure indicated by the height of a column of mercury in millimetres.

Specific Volume of Allyl-Alcohol.—H. L. Buff.—The author first discusses the value of some experiments made by Tollens on the specific gravity of allyl-alcohol, and also bearing upon the labours of Kopp respecting the calculation of the specific volume of fluid compounds. The author next refers to the difficulty of obtaining absolutely anhydrous allyl-alcohol, and lastly communicates that the specific volume of an allyl-alcohol boiling between 96.5 and 96.8 is 74.6.

Preliminary Communication on Bioxybenzoic Acid.—M. Ascher.—Although in the heading this paper is alluded to as a preliminary notice only, the subject is treated of at great length and with a large number of quotations of formulæ. It appears that the author has prepared, by a very circuitous and complex plan, a peculiar dioxibenzoic acid, in small quantity only. The barium salt of this acid has the formula $(\text{C}_7\text{H}_4\text{O}_4)_2\text{Ba}$. The acid is designated as the 2,4 bioxybenzoic acid, but it is entirely different from protocatechutic acid, which, according to the author, should be styled 1,3,4.

Constitution of Chrysanic Acid.—H. Salkowski.—The contents of this paper contain the description of the mode of preparation and properties and formulæ of a series of salts of a dinitro-oxymybenzoic acid, which is formed by the action of nitrous acid upon chrysanic acid. Among the bodies spoken of at length are the mono-ethyl-ether, $\text{C}_6\text{H}_4(\text{NO}_2)_2\text{OCH}_2\text{C}_2\text{H}_5$, a diethyl-ether which, by the action of ammonia, is converted into chrysanic acid, which latter, and also the chrysanic acid ether, are, by boiling with alkalies, converted into dinitro-oxymybenzoic acid, which latter is related to the various isomeric oxymybenzoic acids in the same manner as picric acid is to phenol.

Contribution to our Knowledge on the Colouring Matter of Cochineal.—C. Liebermann and W. A. van Dorp.

Phenol Pigments.—A. Baeyer.—This essay and the preceding paper are reserved for full translation.

Manufacture of Ethylene Bases on the Large Scale.—Dr. A. W. Hofmann.—The eminent *savant* first calls attention in this paper to the opportunity afforded, by the preparation of chloral on the large scale, as carried on in and near Berlin by several firms of manufacturing chemists, of obtaining, in large quantity, some of the by-products of this operation. The author describes, next, the preparation, on the large scale, of chlorhydrate of ethylene-diamine—

of which salt about 1½ kilos. were obtained in the shape of large-sized needle-shaped crystals 10 to 15 centimetres in length. It is the intention of the author to return to this subject, and publish a full account of his researches on the bodies which are formed by the action of ammonia upon the chlorides and bromides of ethylene.

Preliminary Communication.—O. Wallach.—This paper treats on the action of chloral upon aniline and toluidine; but as yet the author's researches are not complete, and the only reason why this short paper is published is that for some time to come this work cannot be completed.

Observations on the Allyl Group.—A. Oppenheim.—This memoir is divided into the following chapters:—Action of chlorine upon trichlorallyl; iodallyl-mercury and preparation of diallyl.

Researches on the Platinum Bases.—P. T. Cleve.—This very lengthy essay, however valuable in a scientific point of view, is not well suited for any useful abstraction. It contains the following sections:—On a fourth isomer of the formula $PtAk_2Cl_2$; on the nitrites of the two platinum bases, PtA_2 ; sulphites of the isomeric bases, PtA_2 ; product of platosemidiamminchlorid with potassa.

Conversion of the Dichlorhydrine boiling at 174° into that boiling at 182° .—H. Hübner and C. Müller.

On a Sulpho-Toluol.—H. Hübner and N. M. Terry.—These papers, although of great scientific value, require, for the proper elucidation of the subject, a series of formulae too lengthy and complex to admit of being here conveniently reproduced.

Journal für Praktische Chemie, Nos. 8 and 9 (double number), 1871.

This number contains the following original papers and memoirs:—

Continuation of Monograph on the Periodides of the Alkaloids.—Dr. S. M. Jürgensen.—This portion contains the following sections:—Tetra-ethyl-stibonium-triiodide; triethyl-sulfon-super-iodide; tetra-ethyl-ammonium-bismuth-iodide; tetra-ethyl-phosphonium-bismuth-iodide; tetra-ethyl-ammonium-bismuth-bromide; tetra-ethyl-phosphonium-bismuth-bromide; tetra-ethyl-arsonium-bismuth-bromide; tetra-ethyl-stibonium-bismuth-bromide; tetra-ethyl-stibonium-bismuth-iodo-bromide; tetra-ethyl-ammonium-bismuth-chloride; tetra-ethyl-phosphonium-bismuth-chloride; tetra-ethyl-arsonium-bismuth-chloride; tetra-ethyl-stibonium-bismuth-chloride; tetra-ethyl-stibonium-bismuth-iodo-chloride.

Simple Apparatus to Serve for Washing, as well as simultaneously Absorbing Gas.—Dr. H. Fleck.—Illustrated with a woodcut essentially required for properly understanding the arrangement and mode of working with this contrivance.

Application of a Reflector to Spectrum Analysis.—Dr. H. Fleck.—Illustrated with a woodcut.

Action of Hydrobromic Acid upon Citric Acid.—M. Mercadante.—The author expected to obtain, by causing hydrobromic acid to act upon citric acid, first a bromated acid, $C_6H_7BrO_6$, and from that, by the aid of nascent hydrogen, tricarballic acid, $C_6H_4O_6$; but, instead of obtaining this result, aconitic acid was formed, which has also been observed to result from the action of hydrochloric acid upon citric acid by Desaigne. This reaction is due to the elimination of a molecule of water from citric acid, and is elucidated by the following formulae:—

Normal Valerianic Acid.—A. Lieben and A. Rossi.—This lengthy essay describes the mode of preparation of the acid alluded to from butyl-cyanide, by boiling it with alcoholic potassa solution. The acid in pure state is a fluid; sp. gr. at $0^\circ = 0.9577$, and at $99.3^\circ = 0.9334$; boils at 185° ; formula, $C_6H_{10}O_2$. The authors describe a series of the salts of this acid, observing that they confirmed, by their researches, the older experiments of Dumas and Stas, anent the acid obtained from the amyl-alcohol of fermentation, that it yields with baryta a syrup-like fluid salt (see *Ann. Chim. Phys.* [2], 49, lxxiii., p. 134).

Continuation of the Researches on the Compounds of Ilmenium and Niobium, and on the Composition of the Niobium Minerals.—R. Hermann.—This exhaustive monograph, to be further continued, is, in spite of its intrinsic scientific value, far too lengthy for any further quotation.

Conversion of Succinic Acid in the corresponding Diatomic Alcohol.—Dr. A. Saytzeff.—This preliminary notice states that the author obtained, by the action of sodium amalgam upon a mixture of chloride, succinyl, and acetic acid in etheral solution, butyl-glycol, while the thereby simultaneously-produced glycol is probably the homologon to ethyl-glycol. The full record of these experiments will shortly be made public.

Cobalt Ultramarine, a Contribution to our Knowledge on the Origin of the Colour of Substances.—W. Stein.—The author first refers briefly to his researches on ultramarine (see *CHEMICAL NEWS*, vol. xxiii., pp. 119, 122, and 204), reminding his readers that a blue colour may result from the intimate mixing of a black and white molecule. Next, this paper contains researches on a sample of cobalt ultramarine, which had been kept for some twenty years in the Museum of the Dresden Polytechnic School. The result of the analysis of that substance led to the following composition, in 100 parts:—Silica, 4.0; alumina, 68.45; cobalt (metal), 20.80; oxygen, 6.75. The composition of the oxide of cobalt present in this ultramarine is $4CoO.Co_2O_3$. The analysis was confirmed by the synthesis of an ultramarine cobalt—viz., by simply igniting the black oxide of cobalt of commerce with alumina.

Ethyl-Diacetic Acid and some of its Derivatives.—A. Geuther.—The first half-page of this paper being only here published, it is reserved for further notice when complete.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, May and June (double number), 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Cotton Seeds.—Dr. F. Flückiger.—This lengthy essay contains, in the first place, a succinctly written botanical description of the several kinds of shrubs and trees from which cotton is obtained; next, we meet here with a histological and morphological minute description of the microscopical structure of the cotton seeds, illustrated by coloured lithographs. The latter portion of this essay is devoted to a well-condensed and very complete review of all that has been done in various parts of the world in reference to the scientific, as well as industrial, researches on cotton seeds and the oil it yields. According to the author, the quantity of cotton seed annually gathered amounts to 1,000,000,000 of kilos., which, under the least favourable conditions, would yield 150,000,000 kilos. of oil.

Method of Air Analysis applied to Photo-Physiological Research.—H. Karsten.—The contents of this paper cannot be rendered intelligible without the reproduction of the woodcuts elucidating the ingenious and complex apparatus here described.

Qualitative and Quantitative Comparison of the Mineral Constituents of a Plant, and of the Constituents of the Soil it has been Cultivated in.—H. Reinsch.—Notwithstanding its intrinsic merits, this lengthy memoir is not well suited for useful abstraction. The author brings forward in this essay, and proves, by experiments made on an extensive scale, some new views concerning the growth and nutrition of plants and their relation to the soil, as well as to the atmosphere.

Poisoning of Bees by means of Yeast.—Dr. R. Mirus.—The main point of interest in this paper is, that a mixture of honey and beer-yeast acts as a poison to bees, in consequence of inducing, when partaken of by these insects, fermentation in the stomach of these animals; the beer-yeast also acts upon bees as a drastic purgative. Neither by microscopical, nor by chemical research, was any other poisonous or deleterious substance found, either in the bodies of the insects or in the mixture above alluded to.

Impurities present in the Reduced Iron, Ferrum Hydrogenio Reductum.—E. Schering.—While this substance has hitherto not been obtained quite free from a more or less large quantity of sulphuretted iron, the author calls attention to the fact—an important one, indeed—that he has met with samples of this medicament which, in addition to the impurity spoken of, also contains oxides and carburets of iron, and even cyanide of potassium, due in all likelihood to the reprehensible practice of preparing the reduced iron from the residues of the preparation of cyanide of potassium from the ferrocyanide of potassium. It is therefore advisable for pharmacutists to test the ferrum hydrogenio reductum they purchase for the presence of the cyanide alluded to.

La Revue des Scientifique de la France et de l'Etranger, July 8, 1871.

This number does not contain any original papers or memoirs relating to chemistry or allied sciences, but there is an interesting paper on the—

University of Strasburg.—E. Aiglave.—Strasburg was once a free city—that is to say, a free and independent republic, just as Hamburg and Bremen are now, and as, during the middle ages, many towns and cities were on the Continent of Europe. As such, Strasburg had a University, which remained in existence until the first Napoleon created what is termed L'Université de France. By the arrangements under which that establishment exists, there was founded at Strasburg a faculty of medicine, of literature, and of sciences, and a school of

pharmacy, and also a faculty of Protestant (Lutheran) theology. This establishment was exceedingly well arranged, and possessed fine collections, libraries, and museums. The Prussian Government intend to establish a very complete university at Strasburg, and, while they have acquired the ceasing of all the rich *matériel* already in that city, intend to endow Strasburg University with £32,000 a year. The French Government is arranging to re-establish at Nancy (now a frontier town) the University of which Strasburg was the see, while Lyons also is mentioned for a similar purpose. It is a happy feature to learn from this and other scientific periodicals that the French nation is becoming alive to the high importance of general sound education, and of largely-extended scientific instruction.

Revue Universelle des Mines, de la Métallurgie, des Travaux Publics des Sciences et des Arts Appliqués à l'Industrie (double number), for the first four months of 1871.

This number contains the following original papers and essays relating to chemistry and collateral sciences:—

Mercury Mines of Almaden, Spain.—José de Monasterio y Corra. This essay, illustrated with a series of engravings, has been written by the author, Inspector General of Mines to the Spanish Government, while sojourning lately at Liège, Belgium, at the request of the editor of this periodical. This valuable memoir, too lengthy for any useful abstraction, contains the following sections:—History of the Almaden mines; situation; geology; veins and seams of ore; mode of working the mines, and extraction of the ore; pumping engines and other machinery required for keeping the workings free from water; ventilation; shifts of workmen; hygienic condition of the workmen.

Note on the Discovery of Four New Seams of Coal at the Collieries of the Grand-Hornu (near Mons, Belgium).—H. Gilpin. Illustrated with maps and engravings.

Influence which the Cession of Alsace and Lorraine to Germany will have on Metallurgical Industry.—Ch. de Cuyper. From this paper it would seem that, not only in a strategic, but also in an industrial and metallurgical way, Germany has got the mastery to such an extent, that even the United Kingdom will be, at no distant day, very seriously affected by recent events in its metallurgical industry and commercial interests.

Les Mondes, July 13, 1871.

This number contains the following original matter relating to chemistry and collateral sciences:—

Record of the Observations on Meteorites seen in Italy during the Months of March and April of the Current Year.—Rev. Father Denza, S.J.—An important contribution to our knowledge of the phenomena vulgarly known as falling stars, minutely described as observed by Italian astronomers.

Brief Biography of the late Ramon de la Sagra.—Dr. Sacc. To most of our readers the name of Ramon de la Sagra will be familiar, in more than one sense. The illustrious *savant* was born at Corunna in 1811, and studied, first, medicine, at Bilbao, afterwards exact sciences, at Madrid. He embarked, while yet a young man, in an industrial enterprise, which unfortunately proved a failure, and in consequence of which he left Spain for Cuba, where, for a period of seventeen years, he was director of the botanic gardens near Havana; while engaged in this capacity, the deceased edited his magnificent "Fauna of Cuba" (12 folio volumes, published by J. B. Baillière, Paris). Later in life, De la Sagra returned to Spain; but it appears that, from some cause or other, he has been compelled to leave that country; and he died on the 25th of May last, at Cortaillad, in Switzerland. The deceased was well known, also, for the great interest he took in the improvement of the general education of his countrymen. In politics he was an ardent but moderate liberal.

New Spectroscopic Process.—Rev. A. Secchi, S.J.—The eminent *savant* describes, in this lengthy paper, an optical apparatus, by the aid of which he has been enabled to see, in the field of the spectroscope, the spectrum of the protuberances and the disc of the sun, so that he could readily distinguish the spots and other particulars as easily as if seen with coloured glasses.

Description of a Self-Acting Gas Apparatus not requiring a Gasholder and not Liable to Explosion.—M. M. Moussard and Kreiger. This description is accompanied by a woodcut essentially required for the proper understanding of the working of this apparatus, which is obtainable from F. Rouille, 8, Boulevard Bonne-Nouvelle, Paris, at a comparatively low price; while, according to the testimony of the Abbé Moigno, who has witnessed the experiments, the light of the gas produced (really a mixture of air with vapours of very volatile hydrocarbons) is very rich and pure, and cheap—exclusive of the duty now imposed in France on the liquids just alluded to—only 15 centimes (about 1½d. per cubic metre) = 35·316 English cubic feet.

NOTES AND QUERIES.

Cement to Resist Nitric Acid.—(Reply to T. Kenyon.)—You are referred to *CHEMICAL NEWS*, vol. xix., p. 287; vol. xx., p. 23; and vol. xxii., p. 48.

Distillation of Wood.—Will you kindly tell me whether there is a work on the manufactures arising from the destructive distillation of wood, and where it is to be obtained?—J. H. MAYOR.

Carbolic Acid.—Will your correspondent, Dr. Ballard, who inserted some time ago a communication in your journal on the above subject, inform me where it can be obtained (for disinfection), without the unpleasant odour usually attaching to it.—CARBOLIC.

Anthracene.—(Reply to Henry Dorsett.)—In addition to what is published (see *CHEMICAL NEWS*, vol. xxiii., pp. 143 and 156), you will find a very good account of the best and most practical methods of preparing anthracene in Dr. Elsner's "Chemisch-Technischen Mittheilungen" for 1869-70, pp. 13 and 14; but this paper is too lengthy for quotation here, and does not admit of being condensed. You may inspect this book at the Library of the Commissioners of Patents.

Skein Silk.—We English dyers have to contend very much against foreign dyed silk weighted with gambia to 323 to the pound. The gambia is forced on the silk with crystals of muriate of tin. Now comes our difficulty: after getting on the weight, how to kill the tin, so as to follow with the logwood to make a black,—we resort to boiling-hot soap-lather; the danger is in making the silk tender. Cao you or any of your readers give me a more rapid and safer mode of killing the tin, without danger to the silk; you must understand it is in the skein, not manufactured.—C. R. STEVENS.

[We think that experimenting is the only means of determining the best mode of killing the tin. The dyeing of silk, especially black, is a delicate matter, and the fibre itself is not such as will stand much *chemicking*, as it is termed.—ED. C. N.]

TO CORRESPONDENTS.

G. F. Ansell.—Received with thanks.

C. E. Craven.—(1). Messrs. Triebner and Co. have just published "A Practical Treatise on the Manufacture of Soaps," by Campbell Morfit, M.D., &c.; it will shortly be reviewed in our pages. (2). The work is in the press.

C. J. Watson.—This correspondent informs us, respecting an extract on "The Phenomena of Vibration" from the *Scientific American* in our issue of July 21st, that the flame examined was a singing flame which required a tube to cause it to sing. The paragraph mentioned the flame of a gas light, in a glass tube to prevent disturbance by air currents.

A Subscriber.—To become a Fellow of the Chemical Society it is necessary that your application be signed by three Fellows who know you personally, and also by two Fellows on general knowledge; fellows are elected by ballot. The Secretary, Burlington House, will supply you with the necessary forms of application, &c.

J. M. Merrick.—We shall be glad to receive the articles.

S. A. Sadler.—Consult the *Transactions of the Royal Agricultural Society*, or article on "Artificial Manures" in Ure's "Dictionary of Arts and Sciences."

A. F. Hargreaves.—We do not know; an advertisement would probably lead to your obtaining the information.

J. Draper.—Address to Messrs. Von Baerl and Co., Worms, Hesse Darmstadt, Germany.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitric Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

THE CHEMICAL NEWS.

VOL. XXIV. No. 612.

THE DICHROISM OF THE VAPOUR OF IODINE.*

By Dr. ANDREWS, F.R.S.

THE fine purple colour of the vapour of iodine arises from its transmitting freely the red and blue rays of the spectrum, while it absorbs nearly the whole of the green rays. The transmitted light passes freely through a red copper or a blue cobalt glass. But if the iodine vapour be sufficiently dense, the whole of the red rays are absorbed, and the transmitted rays are of a pure blue colour. They are now freely transmitted as before by the cobalt glass, but will not pass through the red glass. A solution of iodine in sulphide of carbon exhibits a similar dichroism, and according to its density appears either purple or blue when white light is transmitted through it. The alcoholic solution, on the contrary, is of a red colour, and does not exhibit any dichroism.

THE ACTION OF HEAT ON BROMINE.*

By Dr. ANDREWS, F.R.S.

IF a fine tube is filled one-half with liquid bromine and one-half with the vapour of bromine, and after being hermetically sealed is gradually heated till the temperature is above the critical point, the whole of the bromine becomes quite opaque, and the tube has the aspect of being filled with a dark red and opaque resin. A measure of the change of power of transmitting light in this case may be obtained by varying the proportion of liquid and vapour in the tube. Even liquid bromine transmits much less light when heated strongly in an hermetically-sealed tube than its ordinary state.

ON SORBIN.†

By PROFESSOR DELFFS.

TWENTY years ago M. Pelouze (*Ann. de Chim. et de Phys.* 3 ser., vol. xxxv., p. 222) discovered a crystalline substance in the fruits of *Sorbus aucuparia*, which he called sorbin. Since that time very few chemists have paid attention to this matter, and, as far as I know, nobody in my country succeeded in preparing it again. The principal of one of our greatest manufactories of chemical preparations, to whom I addressed myself, told me that he never found the least trace of the said substance, although he had worked up large quantities of the above-mentioned fruits for preparing malic acid, and to the same result came M. Byschl (*Buchner's N. Repert. der Pharm.*, vol. iii., p. 4), who asserts that there is no ready formed sorbin in the ripe berries of *Sorbus aucuparia*. In my two first attempts of getting sorbin I failed also, but in the last year I succeeded, and at the same time I became aware of the reason of my first failures. When I first tried to get sorbin, I thought it profitable to combine the preparation of malic acid with the prescription given by M. Pelouze for getting sorbin, and, therefore, I separated

the former by means of acetate of lead, before I followed the same way as M. Pelouze. This is the reason, I think, which has prevented the success of myself as well as of other chemists, in the preparation of sorbin.

As I will not trouble you by repeating a method to be found in all manuals of chemistry, it is sufficient to say, that when I kept strictly to the prescription of M. Pelouze, I got a large quantity of beautiful crystals, a specimen of which is contained in this tube. After I had got these I tried to obtain the malic acid from the residue, but I found that the malic acid had quite disappeared. To this, I must add, that the alcoholic fermentation, which takes place after the juice of the berries of *Sorbus aucuparia* has been left a few days in a tepid place, is easier perceived by the formation of carbonic acid than by the smell of spirit of wine. I think it, therefore, not improbable, that there is a connection between the disappearance of the malic acid and the small produce of spirit of wine on the one side, and the formation of sorbin on the other. Suppose the malic acid—commonly called bibasic, and, therefore, apt to form a bimaleate of ethyl ($=C_4H_5O+2C_4H_2O_4+HO$)—assimilates two equivalents of water to this compound, you will have then the equation $C_4H_5O+2C_4H_2O_4+3HO=C_{12}H_{12}O_{12}$, the latter formula of which gives the composition of sorbin.

As what belongs to the preparation of sorbin I have only to add, that the dark sticky lye in which the crystals are formed, can very easily be separated by putting both on a brick. After a few days' repose, the brick has absorbed nearly all the lye, and the pale yellow coloured crystals of sorbin, if dissolved in water and left to spontaneous evaporation, become very soon colourless.

The sorbin belongs to the same group as the mannit, quercit, inosit, dulcitol, pinit, &c., and, as the last syllable is always characteristic in organic chemistry, its name I think, should be changed into sorbit.

Further experiments are required to prove, if the supposed genesis of sorbin is true or not, but, in any case, I am convinced, that there is no sorbin ready formed in the fruits of *Sorbus aucuparia*.

IMPROVEMENTS IN CHLORIMETRY.

By JOHN SMYTH, jun., A.M., M.I.C.E.I., F.M.S.

THE author showed that the use of the milky solution of bleaching powder in chlorimetry is unsatisfactory, and hence was glad to discover a method of securing a clear solution containing all the chlorine, by dissolving it in an alkaline solution. This is conveniently done by adding say 10 grms. of bleaching powder to 20 grms. of soda crystals ($NaOC_2+10HO$), filtering out the precipitated carbonate of lime, which is known to be washed when it no longer discharges the colour of dilute sulphate of indigo, and making up the filtrate by water to 1 litre of fluid. It is a clear, colourless liquid, of the sp. gr. of 1.007; but, if made of sp. gr. 1.233, slightly greenish, having a pleasant oily feeling between the fingers, contrasting favourably with the roughness of the decanted solution of the bleaching powder, with which it gives a precipitate. Most satisfactory results are obtained from it by all the chlorimetric methods, and it has the additional advantage of showing the amount of lime in the sample, by adding a solution of known strength of carbonate of soda until a precipitate is no longer formed. It is manufactured and used in the north of Ireland for bleaching fine linens; and from the ease and accuracy with which its percentage of chlorine was obtained, the author was led to investigate the feasibility of converting bleaching powder into it for chlorimetric purposes, and obtained the above results.

* Abstract of a Paper read before the British Association, Edinburgh Meeting, Section B.

* Abstract of a Paper read before the British Association, Edinburgh Meeting, Section B.

ON THE

CORROSION OF COPPER PLATES BY NITRATE OF SILVER.*

By J. H. GLADSTONE, F.R.S., and ALFRED TRIBE, F.C.S.

In some recent experiments in chemical dynamics, the authors had occasion to study the action of nitrate of silver on copper plates in various positions. They observed that, when the plate was vertical, there was rather more corrosion at the bottom than at the top. This is easily accounted for by the upward current, which flows along the surface of the deposited crystals, and which necessitates a movement of the nitrate of silver solution towards the copper plate, especially impinging on the lower part. It was also found that, when the copper plate was varnished on one side, it produced rather more than half the previous decomposition, and was most corroded at the edges of the varnish. By making patterns with the varnish, this edge action became very evident. This was explained by the fact that the long crystals of silver growing out from the copper at the borders can spread their branches into the open space at the side, and so draw their supply from a larger mass of solution than the crystals in the middle can do; and increased crystallisation of silver means increased solution of copper. This was proved by making the varnish a perpendicular wall instead of a thin layer, when the greater corrosion was not obtained. In a plate completely surrounded with liquid, the greatest growth of crystals is also evidently from the angles. It was likewise observed that, if a vertical plate be immersed, the lower part in nitrate of copper, and the upper part in nitrate of silver, there is greater corrosion about the point of junction; this was attributed to the greater conduction of the stronger liquid.

THE ESTIMATION OF SULPHUR IN COAL AND COKE.*

By F. CRACE CALVERT, F.R.S.

HAVING for many years observed the analyses of the amounts of sulphur existing in coals and coke as published in various works, I have come to the conclusion that the difference observed in the amounts of sulphur found in the same coal by different chemists is not due so much to a difference in accuracy or wide differences of samples as to the various methods adopted to determine the weight of the sulphur. Without entering into the merits of the various processes which have been proposed to effect this object, I only wish in this paper to point out sources of error attending the method which, I believe, to be most usually adopted, which consists in adding to an oxidising *aqua regia* a known weight of very finely powdered coal or coke, leaving it to be digested at a moderate temperature until the whole of the sulphur is supposed to be converted into sulphuric acid, then driving away the great excess of acid, boiling with water, filtering, washing the carbonaceous residue on the filter, and determining the amount of sulphuric acid in the filtrate.

In operating in this manner, there are three serious sources of error. The first is that the sulphate of lime, which many coals contain in considerable proportion, may mislead the analyst, owing to its solubility in water being much increased by the presence of free acid. The figures usually obtained include the sulphur combined with the calcium as well as that existing as pyrites in coal, or sulphuret of iron in coke. It is, however, most important, in a metallurgical point of view, to give the

figures separately, for the sulphur combined with the calcium as sulphate of lime will not leave its strong base to deteriorate the quality of the iron, either in the blast furnace or in any of the subsequent processes of manufacture, whilst the pyrites, although losing part of its sulphur as sulphurous acid, mixes as monosulphuret with the iron, and seriously lowers its commercial value.

It appeared to me, therefore, important to devise a method by which the amounts of sulphur, combined with calcium and iron, respectively, could be determined, and the following process I found to be successful. The finely pulverised coal or coke is boiled for about twenty hours with water containing an equal weight of coal or coke taken. By this means the sulphate of lime or sulphuret of calcium is decomposed, whilst the sulphuret of iron remains unattacked. The residue is then filtered and rapidly washed with boiling water. If a coke has been taken, nitric acid in slight excess must be added to the filtrate to convert the sulphuret of sodium into sulphate, and the sulphuric acid determined in the usual manner. The sulphur found in the residue will then represent the amount present in the coal or coke as pyrites or sulphuret of iron.

The value of a coal or coke for use in the iron manufacture may easily be seriously miscalculated if this difference be not taken into consideration, as may be seen from the subjoined table, which gives the figures found in six samples sent to my laboratory for analysis. It will be seen that by the usual process the coals would be condemned as unfit for use in the manufacture of iron, while, in fact, they are well adapted for that purpose.

	Old process.		New process.		In washings.		Difference between processes.

3.	1.78 1.73	1.75	0.89 0.85	0.87	0.85 0.88	0.87	0.88
4.	1.37 1.38	1.38	0.50 0.53	0.52	0.98 1.00	0.99	0.86
5.	1.41 1.42	1.42	0.54 0.56	0.55	0.91 0.94	0.93	0.87
6.	1.58 1.60	1.59	0.68 0.70	0.69	0.97 0.99	0.98	0.90

The second objection to the method of analysis above given is that if the evaporation of the *aqua regia* be carried too far a subsulphate of iron is sometimes formed, which no amount of boiling with water will remove from the carbonaceous mass, and the chemist may thus obtain too small a quantity of sulphur in the coal or coke under examination.

The third objection is that in an acid liquor, especially if any nitric acid be present, the amount of sulphur found will always be much below the actual quantity present, owing to the fact that the formation of sulphate of baryta is, in some measure, prevented by the presence of the acid, the proportion, of course, varying with the concentration of the acid. Thus I showed some years since that the non-formation of sulphate of baryta could reach the large proportion of 14 grs. of sulphate of baryta in 1000 grs. of nitric acid, of sp. gr. 1.21, an amount greatly exceeding that produced from the sulphur usually found in 100 grs. of coal or coke.*

As the amount of nitric acid left in the liquor is unknown, the extent to which the formation of sulphate of baryta has been prevented is also unknown, and, consequently, the figures obtained cannot be relied upon.

I cannot impress too much upon young analysts the importance of paying attention to the fact that the formation

* Abstract of a Paper read before the British Association, Edinburgh Meeting, Section A.

* Read before the British Association, Edinburgh Meeting, Section B.

* "On the Solubility of Sulphate of Baryta in Acid Solutions," *Memoirs of the Manchester Literary and Philosophical Society*, vol. xiv. 1856.

of sulphate of baryta is prevented by, and is in ratio to, the excess of nitric acid existing in the fluid, and the common belief, that leaving the liquor to stand twenty-four hours, overcomes the objection, is only approximately true, as only a part of the sulphuric acid is precipitated, while part remains in solution.

To avoid these two latter objections, I always, after concentrating the acid liquor, add carbonate of soda in excess and heat to near the fusing-point. By this means the iron, silica, and alumina, are rendered insoluble; the mass is then treated with water, washed well, and the filtrate made slightly acid with acetic acid. The sulphate of baryta is thrown down from this liquor immediately and completely.

If the dry oxidising process is followed, that is, the addition of the finely pulverised coal or coke to a fused mixture of carbonate of potash and of chlorate or nitrate of potash, then two of the above objections are removed, viz., the non-formation of sulphate of baryta in an acid liquid or the production of a basic sulphate of sesquioxide of iron, but there still remains the objection of the determination of the sulphuric acid of the sulphate of lime, together with that of the pyrites; and, further, I have never obtained a satisfactory determination of sulphur in an organic product or in coal when I have employed this method. There has always been a loss of sulphur.

PRELIMINARY NOTE ON OXY-CANNABIN.

By T. BOLAS and E. E. H. FRANCIS.

WE have ascertained that oxy-cannabin contains nitrogen, which was overlooked in our original examination (*Journ. Chem. Soc.*, xxii., 417). Subjoined are the analytical results obtained with a carefully purified specimen.

This substance is still under investigation.

OBSERVATIONS ON THE COLOUR OF FLUORESCENT SOLUTIONS.

By HENRY MORTON, Ph.D.,
President of the Stevens Institute of Technology.

As the result of a series of experiments to be presently described, I have come to the curious conclusion that all the familiar fluorescent solutions, such as the tincture of turmeric, of agaric, of chlorophyll, and the solution of nitrate of uranium, emit light of the same colour by fluorescence—viz., blue, identical with that developed by acid salts of quinine. This blue, however, in all cases, that of quinine included, being, not of a single tint or refrangibility, but yielding a continuous spectrum in which the more refrangible rays predominate.

My attention was first drawn to the subject by observing that a specimen of mixed asphalt, which is here largely used in the preparation of pavements, yielded a light yellow solution with alcohol which fluoresced blue, and

an orange solution with turpentine which fluoresced green. It at once occurred to me that the green colour was simply due to the absorptive action of the coloured solution, and not to the development of green rays.

Examined with the spectroscope, the seemingly green fluorescence showed no increase in the green or yellow part of the spectrum, as compared with the blue fluorescence, but only an absorption of the red and violet ends.

When, however, a piece of fluorescing canary-glass or solid nitrate of uranium was examined, the green light was, as is well known, of course, largely augmented.

I also found that when, by filtration through animal charcoal, the solution in turpentine was reduced in colour, the green tint of the fluorescence disappeared in a corresponding degree.

This alone would, however, have proved nothing, as a green-fluorescing matter might have been absorbed by the charcoal, but in connection with the spectroscopic result it was of interest.

I next took up for examination the tincture of turmeric. This is set down in standard works, such as those of Du Moncel, as fluorescing red.

This solution, when concentrated, has a rich orange-red colour, and the jacket of a Geissler tube being filled with it all the light reaching the eye from the electric discharge within is of a deep orange or red colour. If, however, the solution is simply diluted until its colour is reduced to a rich yellow, the fluorescence appears green. The same result follows from filtration through bone-black, with a marked increase in the amount of fluorescence visible as compared with the red solution.

By continuing the decolouration until the liquid is of a very light tint, its fluorescence is distinctly blue.

The results with the spectroscope, when it was applied in this case, were the same as with the solution of asphalt. Such, also, is the case with tinctures of chlorophyll, which, when fresh and green gives a green light, and when old and brown a grey colour.

Finally, I took up the nitrate of uranium, about which such contradictory statements have been published. This salt, in its solid state, gives a brilliant green fluorescence, whose spectrum is figured by Becquerel, and abounds in green rays; but in solution it gives a very feeble fluorescence, far inferior to that of turmeric, and of no more green tint than would be due to its yellow colour.

So, in fact, says also the spectroscope.

From these results, it would seem that the molecules of fluorescent bodies in solution are not capable of restricting their vibrations to limited rates, but move at rates corresponding with all refrangibilities, having simply an excess of the higher ones; though the same substances in the solid state may act quite differently, as in the case of nitrate of uranium, and possibly the fluorescent material in the asphalt, which may be related to the solid hydrocarbon fluorescing green which Becquerel mentions.—“La Lumiere,” vol. i., p. 382.

In this general connection, let me mention that I have observed that, while the acid salts of quinine generally are fluorescent, the chloride is not, and that hydrochloric acid will decompose the acid sulphate, so as to destroy its fluorescence. There are several other points in connection with this and the foregoing subject which I must leave for a subsequent discussion.

ON THE USE OF POROUS CONES IN FILTRATION.

By CHARLES E. MUNROE.

THE sulphides of arsenic and antimony being quite easily obtained have long been regarded as furnishing the readiest and best means for the estimation of these two elements. A serious objection has, however, arisen in the fact that they must be determined upon weighed

filters, and that paper filters cannot be dried above 100° without danger of loss. Hence, a filter which could be weighed easily and withstand a high temperature became a desideratum.

Taylor* accomplished this with sand filters, and obtained some excellent results. This method, however, requires experienced and careful manipulation, reasons which will probably prevent its being generally used.

Under these circumstances the idea of using a cone made of very porous earthenware, and as a substitute for the paper filter, presented itself to me, and has been carried out in the following manner:—

The cones† are made of very light, porous earthenware, and have an angle of about 60°. They are used in the following way:—

A section of a seamless rubber tube, *a*, is stretched around the mouth of a funnel, *b*, preferably a Bunsen funnel, allowing a portion of the tube to project above the top. This part will immediately arrange itself at right angles to the top of the funnel; into the circle thus formed the

cone, *c*, is put. It is then connected with the Bunsen pump. When the cone is moistened and the pressure applied, the rubber band forms an air-tight joint, and the liquid runs through with great rapidity. Before the cones are applied to quantitative work they must be carefully washed, first with concentrated chlorhydric acid, then with distilled water, dried, and weighed. A small porcelain crucible was always kept at the balance in which to weigh them. With this apparatus the following results have been obtained.

A sample of ordinary crystallised potassio-antimonylic tartarate gave—

Grms.	Grms.
(1). 1.1069 gave 0.5570 Sb_2S_3 = 35.94 per cent Sb.	
(2). 1.6985 " 0.8550 " = 35.96 " "	
Mean 35.95.†	

A specimen of the same salt, carefully re-crystallised, gave upon analysis the following data.

Grms.	Grms.
(1). 0.7755 gave 0.3955 Sb_2S_3 = 36.40 per cent Sb.	
(2). 0.6050 " 0.3085 " = 36.42 " "	
Mean 36.41.	

Mr. W. Lincoln also made an analysis of the same salt by means of the cones, and kindly permits me to use his results.

Grms.	Grms.
(1). 0.4683 gave 0.2388 Sb_2S_3 = 36.41 per cent Sb.	
(2). 0.8135 " 0.4144 " = 36.38 " "	
Mean 36.40.	

In all of these analyses $\text{Sb} = 120$.

The Sb_2S_3 was precipitated in the manner recommended by Sharples.* It is necessary that the boiling should proceed for some time, a brisk current of sulphydric acid being passed through the liquid. The precipitate is then filtered upon the weighed cone, and the whole dried in an air-bath at 300°. The antimonious sulphide is at this temperature converted into the gray crystalline modification.

No formula has yet been found which agrees with either of the percentages obtained. As the atomic weight of antimony is differently stated from 120 to 122, this is easily explained.

It is unfortunate that the atomic weight of antimony is yet so uncertain, but it is hoped that these results, agreeing so closely among themselves, will be accepted as proving the value of the process.

Arsenious Oxide.—This was the next substance analysed. The sulphide was precipitated in the usual manner, but it was noticed that by having the solution decidedly acid and passing through it a very rapid stream of sulphydric acid, that the sulphide was obtained in a more granular condition.

The precipitate can be dried with impunity at 120°. At 140° the lemon-yellow sulphide commences to change to red, and at 180° is completely converted into the liver-red variety.

With ordinary commercial arsenious oxide, the following results were obtained.

Grms.	Grms.	Found per cents.	Theory per cents.
(1). 1.7940 gave 2.2260 As_2S_3 = 75.64		75.76	As.
(2). 0.5770 " 0.7165 " = 75.84		"	"
(3). 0.8520 " 1.0579 " = 75.68		"	"
Mean 75.72			

Mr. Lincoln obtained as the result of two analyses:—

Grms.	Grms.	Found per cents.	Theory per cents.
(1). 0.8926 gave 1.1087 As_2S_3 = 75.76		75.76	As.
(2). 0.8145 " 1.0128 " = 75.77		"	"
Mean 75.76			

These results show that this process renders the estimation of antimony and arsenic one of the simplest and most accurate operations in quantitative analysis.

The cones can be used repeatedly and can replace paper filters in every case. They will, undoubtedly, be found to be of great value in commercial work, for drying crystals and filtering corrosive liquids. As they will stand sudden changes of temperature without breaking, they can be substituted to advantage in many cases for crucibles.

In closing, I desire to return my sincere thanks to my kind teacher, Dr. Gibbs, who has furnished me with the material for these investigations, and has aided me by his counsels and advice.—*American Journal of Science.*

ON THE ORIGIN OF THE DIAMOND.†

By the Rev. W. B. CLARKE, M.A., F.G.S.

(Concluded from p. 66).

Diamonds in Russia.

RUSSIA is a country in which diamonds are also found, but sparingly, as near Bissersk and Chrestovodsvingsensk in the Ural chain; the detritus in which they occur being made up of angular fragments of chloritic, talcose, and

* *American Journal of Science*, II., vol. xlv., p. 215.

† Much credit is due to the firm of A. W. and H. C. Robertson, of Chelsea, Mass., who, by their superior mechanical skill, have aided me much in accomplishing the desired result.

‡ Taylor obtained as the mean of three analyses 36.08.

* *American Journal of Science*, II., vol. i., p. 248.

† From the Anniversary Address delivered to the Royal Society of New South Wales.

quartzose rocks. The former of these places was mentioned in 1831 in the "*Gornoi*" *Journal of Petersburg*; and in 1839 Baron von Meyendorf stated to the Geological Society of France that diamonds had been discovered in two different localities, and that they had been found in a microscopic form in native iridium which had been brought to Paris. (*Bull.*, ii., 314).

The first Ural diamond was found at Bissersk in 1829 after Humboldt's visit to Count Polier; three others were found afterwards in that year. In 1830 other three were found. M. Karpoff, a mining officer, shortly after was deputed to carry on the search, and four were discovered, which are described as colourless, diaphanous, smooth, and very bright, with 42 triangular facets. One was broken in two.

Thirteen others were taken, the last in July, 1833, from the Adolphskoi Mine, and were used by the Countess Polier in decoration of her church images. One weighed $\frac{1}{2}$ of a carat. Their forms showed from twelve to forty-two curved facets, smooth and sparkling. In 1831, however, a few were found in the gold land of M. Medjer near Ekatherinburg. One was given to the Institute of Mines by his son after the father's death. It was a rhomboidal dodecahedron with rounded edges and translucent, weighing $\frac{1}{2}$ of a carat. (*Bull. Geol. Soc. de France*, vol. iv., p. 100, 1833). The information here given was received from Count de Cancrine, Russian Minister of Finance.

Sir Roderick Murchison, in 1841, saw forty diamonds from the Adolphskoi rivulet; but as the gold found with them did not pay, no further search was made for diamonds. Three other localities have also been named (*Geol. of Russia and the Ural*, 1845, p. 641), in two of which one diamond and in the third two diamonds were found.

Sir Roderick considers that the itacolumite of Brazil occurs in various parts of the Ural, where it was detected by Colonel Helmersen, and adds, what seems to bear upon certain conjectures previously mentioned. He says:—"We may add that as carbonaceous grits of the Devonian and carboniferous periods exist, it is very easy to conceive how these masses, like other sediments to which we have previously alluded, have been transmuted into the quartzose micaceous schists which occur in the chain, and how the diamonds have been derived from them and deposited in the auriferous gravel."

Finally, I may remark that osm-iridium found on the Cudgong occurs in three places near the Ural, as well as in South America and in Canada, in gold diggings with which diamonds are, as we have seen, generally associated. Moreover, cinnabar found on the Cudgong is also associated with the diamond detritus of Brazil; and as the mode of its occurrence is precisely that in which it presents itself in the Gilbert gold-field of North Queensland (as I learn from Mr. Daintree), and also in that most wonderful gold-field on the River Thames in New Zealand (as Dr. Hector has stated), as well as in Otago, *i.e.*, not in lodes but as a member of drift deposits, there is a sort of union between these and other regions in which the diamond is found. Drift or alluvial cinnabar is not less remarkable than drift diamonds; and I believe at present no lode has been detected.

In California cinnabar is said to be brought up by *solfatara* action. (Phillips in *Phil. Mag.*, Dec., 1868, p. 431). It may, therefore, be that the Cudgong mineral is due to the action of former hot springs. The account given by Mr. A. Phillips respecting the "Chemical Geology of the Gold Fields of California" in the paper cited above, justifies the further inference that silicated waters may also have operated in coating and cementing pebbles and fragments of rocks at Cudgong as they have done in California. He even shows that quartz veins holding gold and coloured by pyrites, as well as auriferous pyrites itself, have been formed in recent times by the action of aqueous solutions.

Diamonds in Borneo and Africa.

In the southern ravines of the Rotos Borneo chain, which is composed of serpentine, diorite, and gabbro, which run north and south, there is a deposit of red clay with fragments of quartz, in which spangles of gold, magnetic iron, platinum, and also osmium and iridium are met with, the whole reposing on serpentine. In this clay, on the western slopes, diamonds are found over fragments of sienite and diorite, and with the ores above named. Black quartz with pyrites and plates of platinum are there the indications of diamond, and, according to M. Louis Horner, this quartz belongs to the Serpentine. (See *d'Archiac*, vol. ii., p. 333).

So varied, yet, to some extent, so consistent with each other, are facts connected with the history of the diamond. That its mode of production in all countries may have been the same is very probable; but that origin, it must be said, obtains little illustration from the various geological conditions with which it is associated. Perhaps this very variety, whilst setting dogmatism at defiance, may serve as encouragement to the close observation of practical prospectors.

Of African diamonds we have only heard much of late. Knowing that they are generally found with gold, and that Africa contains numerous auriferous regions, it might have been anticipated that diamonds would have had a greater celebrity in that vast country, forming a quarter of the globe, than they have had in modern time.

But though Heeren has shown that there was a considerable trade among the ancient Carthaginians in diamonds brought from the interior of Africa, the only record I can find in modern times of the existence of diamonds in that part of Africa is of three shown at the Exhibition of the produce of Algiers. They were found in the Goumel River, in the province of Constantine, and were given up in payment to M. Peluzo, the Sardinian consul at Algiers, by an Arab who wished to know their value, saying that they were found in the sand of the Goumel River, with gold. One of these is deposited in the School of Mines at Paris; the second was purchased by M. Brongniart for the Museum of Natural History; and the third by M. de Drée. The Arab had several others. M. Rozet says, however, that he had acquaintance with the jewellers of Algiers, and had never heard of diamonds found in the province. The facts stated are on the authority of Dufrenoy and the Secretary of the Geological Society of France.

In Southern Africa diamonds were reported to have been discovered in 1867. After the announcement of the new find, Mr. Gregory, a well-known London mineralogist, who went to Africa on behalf of the great diamond merchant, Mr. Emanuel, sent to the editor of the *Geological Magazine* (December, 1868) an article denying the statement, and declaring it a "hoax," "imposture," or a "bubble scheme." To this Dr. W. G. Atherstone, F.G.S., a resident of Graham's Town, Cape of Good Hope, replied (May, 1869) refuting the charge, and declaring that twenty-one diamonds were known to have been found either on private or Government land, and thirteen of these were bought by persons of credibility, one of them the Governor of the colony, and another by a lapidary. Dr. Atherstone contradicts Mr. Gregory's account of the geology of the district, the latter asserting that all the rocks are igneous or their derivatives, and the former declaring that the rocks are fossiliferous, of the *Dicynodon* beds (which, by the way, brings them into relation with some of our Australian rocks); and that Mr. Wyley (an accepted geological authority) had, years before this controversy, shown that there was an intimate relationship with the Indian diamond region of Bangnapilly, and that Dr. Shaw had described the African district in the *Graham's Town Journal* of the 20th January, 1869, pointing out also the same resemblance.

In the *Journal of the Society of Arts*, of the 13th February, 1869, is a list of the diamonds by Mr. Chalmers;

who, as well as Mr. Radeloff, a Missionary, asserts that one of them was found near Pniel, by a Griqua.

Mr. Gregory, in answer to this reply, explains some personal remarks of his own, and admits the existence of Dicyonodon relics, but *south* of the district alleged by Dr. Atherstone. And thus stood the matter till 1870. It now appears that diamonds have been found in vast quantities and that many magnificent and valuable stones have been disinterred. They are found on the surface of a calcareous conglomerate near the frontier of the Orange River territory, and are said to vary in weight from 6 to 13 carats; some of them reach 150 carats. The diamonds are accompanied by garnet, topaz, and other hard minerals.

It may be as well to state here that diamonds have occasionally been found in our sister colony of Victoria, and have been recorded by my friends, the Rev. Dr. Bleasdale, Mr. Ulrich, and Mr. Brongh Smith, the latter of whom, in his recently published valuable official work on the "Gold-fields of Victoria," mentions sixty small diamonds of little value from Beechworth, taken out of, or near to, the usual "wash dirt" of the diggers, varying in weight from one-eighth to two carats and a half.

In 1865, fifteen more diamonds were also procured from the Woolshed diggings.

It is said also, that some small diamonds have been found at the Echunga gold-field S. E. of Adelaide, in South Australia.

At the present time, therefore, New South Wales is the diamond colony of Australia.

MINERALOGICAL NOTES FOR 1870.*

By W. H. WAHL.

New Minerals.—From various available sources of reference it appears that during the year 1870 about eleven new species have been added to the catalogue of minerals, with the usual abundance of new varieties. The following historical list will suffice to give a general idea of the character of the new additions.

Glaukopyrite.—Announced by Professor F. Sandberger, occurs at Guadalcanal in Spain, associated with calcite, tetrahedrite, pyrrargyrite, and sulphide of antimony. It is described as occurring in rounded aggregations, which, when magnified, are found to be composed of a series of thin layers. The structure is mainly finely granular. Crystals are not sufficiently developed to be definitely determinable, but Sandberger suspects them to belong to the orthorhombic system. He also believes that he has detected twins and triplets, bearing a general resemblance to those of cerussite. The mineral is described as follows:—Lustre, metallic; colour, light lead-grey, approaching tin-white; streak, greyish-black; hard., 4; specific gravity 7.181.

The chemical examination gave the following as its constitution.

Sulphur	2.36
Arsenic	66.90
Antimony	3.59
Iron	21.38
Cobalt	4.67
Copper	1.14

The species approaches nearly to the geyerite of Bréithaupt, but differs in colour, specific gravity, and in containing copper. It would fall in Dana's pyrites division as a member of his marcasite group.

Rabdionite is the name assigned by Von Kobell to a new metallic mineral, belonging to the class of hydrous oxides of which wad and asbolan are representatives. It differs, however, from the latter, which it approaches very nearly in chemical composition, in several important

particulars. It is crystallised, occurring in short prisms; it has more water, and is more readily fusible. Its characteristics are described as follows:—Colour, black; matt; streak, dark brown; very soft, so that taken between the fingers it readily rubs away, leaving a stain behind.

Namaqualite.—Church describes under this name a new copper ore, from Namaqualand, South Africa. It is described as occurring in thin, fibrous masses, alternating with silicate of copper. Colour, light blue; lustre, silky; hardness, 2.5; specific gravity, 2.49. It consists mainly of oxide of copper, alumina, and water, with small quantities of magnesia, lime, and silicic acid.

Phosphorchromite.—Occurs at Beresowsk upon listwänite, associated with crocoisite and pyromorphite. It occurs in spherical aggregates, the surfaces of which display minute crystal facets. Internally, the spheres are partly crystalline and partly dense in texture. The mineral is described by R. Hermann as follows:—Colour, dark green; streak, lighter; hard., 3; sp. gr., 5.80. The analysis gave:—

Plumbic oxide	68.33
Cupric oxide	7.36
Ferrous oxide	2.80
Chronic acid	10.13
Phosphoric acid	9.94
Water	1.16

Epiboulangerite.—Websky describes a new ore from Altenberg, occurring with mispickel, blende, galena, and pyrites. It occurs in needles of a dark grey colour. Though not suggested by the author, it may prove to be analogous in crystallisation to antimony glance, as it is, in chemical constitution. It differs from Boulangerite, of which it is doubtless a changed product, in containing from 21 to 22 per cent of sulphur.

Amblystegite.—G. Vom Rath gives this name to a new member of the pyroxene group containing alumina. The mineral occurs in the curious sanidin bombs from the remarkable volcanic region of Lake Laach, in the Eifel. The new mineral was long held by Wolf, the well-known historian of Laach minerals, to be an olivin, to which its crystallisation (orthorhombic) bears a close resemblance. The pyramid is, however, much more obtuse (measured over the macrodiagonal edge, it gives $125^{\circ} 58' 1''$, and the dimensions of the axes are determined to be $a:b:c = 0.97:1:0.57$). Its cleavage is described to be inappreciable; hard., nearly 7; sp. gr., 3.4; colour, brown to reddish brown; lustre, adamantine. Chemical composition:—

Silicic acid	49.8
Ferrous oxide	25.6
Magnesia	17.7
Alumina	5.05
Lime	0.15

Uranotil.—Boricky gives this name to a mineral occurring in a drusy quartz which coats the surface of feldspar at Walsendorf, in Bavaria. The character of the occurrence is in fine needles, which Von Zepharovich determines to belong to the orthorhombic system. The needles display frequently a radiated structure. Colour, lemon-yellow; sp. gr., 3.95; streak, lighter. The mineral blackens before blowpipe. Constitution:—

Uranium sesquioxide	66.752
Alumina (ferric oxide)	0.511
Lime	5.273
Silicic acid	13.781
Phosphoric acid	0.448
Water	12.616

Both in crystallographic and chemical character it approaches the uranophan of Websky.

Jacobsite.—A new spinell is described by Damour under this name. It crystallises in octahedra, which are frequently much distorted. Colour, black; lustrous, opaque; hard., cuts glass; sp. gr., 4.75. It contained, according to

* From advance-sheets of the *Journal of the Franklin Institute* Communicated by the Editor.

analysis, 4.21 per cent of peroxide, and 20.57 per cent of the protoxide of manganese. The peroxide constituent is chiefly iron. Small quantities of magnesia and zinc oxide are also present. It may, therefore, be termed a manganese spinel. It occurs at Jacobsberg, in Sweden, in crystalline limestone, associated with silvery mica and particles of native copper.

Gümbelite.—Named by Von Kobell in honour of the geologist Gümbel; is described as a greenish-white mineral, of a pearly or silky lustre; translucent, soft and flexible, and like asbestos to the touch. Occurs in Oberfranken. It consists essentially of a hydrous silicate of alumina, containing likewise a small proportion of potash and ferric oxide.

Milarite.—A new Swiss zeolite occurring in a granite rock in company with smoky quartz, orthoclase, apatite, chabacite, &c.; is described by Professor Kengott. Its crystallisation is hexagonal, the forms being small but sharp, and combinations of prism and pyramid of both orders (the polar interfacial angle of pyramid = $144^{\circ} 46' 5''$). The analysis shows it to be a hydrous soda, lime, and alumina silicate. Its name is derived from its occurrence in the Val Milar. Colour, white to green; hard., 5.5-6.

It will be noticed that Gmelinite, which approaches very nearly in chemical character, presents a further resemblance to the mineral just described in its crystallisation, which is hexagonal (holohedric). The angle of its pyramid is $142^{\circ} 25'$, a variation of but 2° from the measurement which Kengott announces for Milarite.

Hessenberg describes likewise another zeolite from the volcanic region of Santorin. The crystals are short orthorhombic prisms. Before blowpipe it swells considerably and fuses readily to white glass. Prof. Hessenberg describes it as very closely resembling epistilbite. From the similarity, almost identity, of the angle of the prism (the difference scarcely amounts to 1°), it would seem highly probable that the two were the same.

Sandberger describes several new hydrated phosphates, one of which, a phosphate of lime, is analogous to the hydrated phosphate of copper, known as libethenite. The crystals are colourless, belong to the monoclinic system, and possess a prismatic habitus. No name has as yet been proposed for it.

Simonyite is a new sulphate, found in the salt works at Hallstadt, and described by Tschermak. It occurs associated with rock-salt and anhydrite, chiefly in thin layers of a bluish-green colour, presenting here and there a crystalline form, which is announced to be monoclinic. It is a hydrous magnesia-soda sulphate.

Of the numerous varieties which have been announced, the following seem to be the most interesting:—

Lithiophorite.—An ore of manganese, containing lithia. It is amorphous, occurring in thin layers; also pseudomorphic after calcite. It colours the flame intensely red. It is found in the granite of Schneeberg, Schwarzenberg, and Johanngeorgenstadt—generally coating quartz. The granite is much decomposed, and with the spectroscopic gives distinct indications of the presence of lithia.

A new Olivine.—Roepper gives the following as the composition of a mineral occurring in crystals of an inch or two in length, at Sterling, N. J. It is found associated with willemite, Franklinite, Jeffersonite, and spinel.

Silicic acid	29.90
Iron protoxide	35.60
Oxide of manganese	16.90
Oxide of zinc	10.66
Magnesia	5.81
Insoluble	1.03

The crystals were weathered externally, but within were bright. Colour, dark-green to black; hard., 5.5-6. A zinc deposit was obtained with the blowpipe. The crystallisation and analysis prove it to be an olivine. The proportion of zinc and manganese in its composition make it a most interesting variety.

The same author describes a *manganese dolomite*, from or near the same locality. It is a rosy-red mineral, occurring in a vein of apple-green willemite. It possesses distinct rhombohedral cleavage. Hardness = 4; sp. gr., 3.05. An analysis gave as much as 43.5 per cent of carbonate of manganese, 50 per cent of carbonate of lime; the remainder consisting of carbonate of iron and magnesia. Accordingly Roepper characterises it either as a dolomite in which the magnesia has been replaced almost entirely by manganese, or a diallogite, in which a large proportion of the manganese has been replaced by lime.

Hallite, a micaceous (or chloritic) mineral from Chester county, Pennsylvania, has been announced by Leeds. It is flexible, of a brownish colour, and occurs in plates of various sizes. It is believed to possess distinguishing optical properties, though no investigation of the subject has yet appeared.

Metacinnabarite.—G. E. Moore has announced the occurrence, in Lake county, California, of an amorphous sulphide of mercury in a siliceous gangue, in company with cinnabar. It frequently covers crystals of pyrites, and is filled with small cavities in which are found crystals of cinnabar. The colour is greyish-black; streak on porcelain, pure black; hard. = 3; sp. gr., 7.7. It gives all the reactions of cinnabar, with which it is identical in composition. The author very properly identifies it as the variety of sulphide obtained in the laboratory as an amorphous black powder, upon precipitating a soluble mercuric salt. He proposes the name given above to designate the variety.

A LECTURE EXPERIMENT.*

A NUMBER of devices, some of them simple, others complex, have from time to time been described for showing the reciprocal combustion of the elements of water, and experiments of a similar nature.† Most, if not all of these, however, as will be found upon testing, either do not entirely remove the danger of an explosion from the operator, or they require the exercise of an unusual amount of care and dexterity to be used with success.

The accompanying arrangement, which is of the most simple character, and which we saw for the first time on the lecture table of Professor Himes, we have since repeatedly used to show the burning of oxygen, air, chlorine, &c., in hydrogen, burning gas or hydrocarbon vapours. The experiment can be performed with such ease that it is worthy of notice.

The arrangement consists of a cylinder of glass, about a foot or a foot and a half in length (the kind used commonly as chimneys for the argand-burner can be had of proper length). This is furnished above and below with a cork; the one at the upper end has one, that below has two, glass tubes of the form shown in figure. The whole affair is supported from the retort stand. The hydrogen (in the H and O experiment) is admitted through the upper tube, when it has completely displaced the air it is ignited below—the cork having been removed—and the

* From advance-sheets of the *Journal of the Franklin Institute*. Communicated by the Editor.

† Ber. d. Deutsch. Chem. Gesell., iii., pp. 479, 930; *Journal of the Franklin Institute*, lxi., 210.

supply is regulated until only a weak hydrogen flame remains. The oxygen supplied through the straight tube in the lower cork, is now turned on slightly, and the cork fitted into its place. The flame of hydrogen at the opening is extinguished, but the oxygen, in passing up through it, is ignited, and burns now in the centre of the cylinder. The surplus of the hydrogen escapes now from the second tube below, and can be there ignited. This last flame serves the purpose of a good indicator, by which the supply of gases in the cylinder can be regulated, and which, of course, leaves the size of the flame at the will of the operator. Once in operation, the experiment may be left to take care of itself for the remainder of the hour.

ON J. STODDART'S
PLAN OF CONCENTRATING SULPHURIC ACID
BY MEANS OF
HEATING AND BLOWING AIR THROUGH
THE ACID.

By F. BODE.

THE author, having seen in the first number for June of *Dingler's Polytechnisches Journal* a translation of the short paragraph, written by M. J. Stoddart, and published at page 167, vol. xxiii., of the *CHEMICAL NEWS*, has sent to us a loose sheet taken from *Dingler's Polytechnisches Journal* (first number for July), with the request that a translation should be made of the following lines containing observations on the plan of M. Stoddart, only briefly set forth *loco citato*.

F. Bode says:—The boiling-point of sulphuric acid at 60° (1·7 sp. gr.) lies between 190° and 200°, but an acid of the strength just indicated is always obtained when it is run off from the pans at a temperature of from 185° to 190°; according to Stoddart, it would only be necessary to raise the temperature 40° less than is otherwise required. Stoddart has not communicated, in his very brief notice, what saving of fuel and of labour his process yields, as compared with the process in ordinary use. When the pans are well and rationally constructed, and the fire-place properly arranged, 1 cwt. of 60° B. acid may be obtained from acid at 50° by the combustion of from 16 to 18 lbs. of coals of average quality; although the author (F. Bode) knows quite well that in many instances, owing to badly-constructed fire-places and pans not well arranged, as much as double this quantity of fuel is required for the production of the same effect. It would require the setting forth of a great many conditions to enable me to say how much fuel is required to heat acid already at a temperature of 150° further to 190°; but it is clear that the less expenditure of fuel, resulting from having only to heat to 150° instead of to 190°, would not bring on any real gain obtainable from the new (Stoddart's) process. Next comes the point that the air to be blown through the hot acid has to be compressed, even though it be only feebly. By passing through the acid, the air will become hot, and thereby acquire the property of taking up more aqueous vapour than it can take up while cold; but the heating of the air necessarily causes the cooling of the acid, and this loss of heat has to be met by the expenditure of a fresh quantity of fuel. The blowing of air through the acid will either require expenditure of fuel or manual labour not required by the usual mode of concentrating the acid. I should, however, observe that the withdrawal of heat by the blowing through of air may, under certain premises, be rendered very small. In order to make the air which is forced into the acid take up as much water as possible, that air should be brought largely into contact with the acid, and should become as warm as possible; but this arrangement necessarily involves a high column of liquid for the air to pass through, consequently the use of a very deep pan. The

pans now generally in use for concentrating acid to 60° B. are generally not filled deeper with acid than to a height of 0·35 metre, and, for the blowing of air through the acid, this height appears rather too small; yet the construction of pans of greater depth is not to be recommended, for a great many reasons. In the first place, deep pans containing a high column of acid will require (since the pans are made of lead, which is apt to bend and give way, by becoming hot, under the weight and pressure of the acid), to be supported at the bottom all over. This support, although best made of cast-iron plates, is often simply made of slabs of burnt fire-clay; but these slabs, in the first place, prevent the ready transmission of the heat from the fuel to the pan and the acid therein contained: moreover, these slabs not only absorb and retain heat which is not utilised, but they interfere with the giving off of the heat of the gases of the combustion to the pans, and thereby cause that, if pans are constructed so as to yield, in a given time, a certain quantity of acid of 60° B., either a larger number of pans will be required (under the conditions alluded to), or a pan will have to be made so as to be exposed to a larger surface of fire. These considerations apply to deep pans, and so do the following:—The destruction of the lead of which the pans are made is generally observed to take place chiefly, if not exclusively, at the bottom, unless, indeed, exceptionally, either from defects of the lead or from construction. There is no reasonable ground to suppose that, of two pans of equal size at the bottom, the pan with greater depth and consequently higher column of acid therein, should last longer than a shallow pan, and we must therefore assume the durability of each of these pans to be the same; but it is then clear and evident also that a shallow pan will be, in a given time, more advantageously worn, because the weight of lead contained in the sides of such a pan is less. In order to guard against the spirting of acid, and, consequently, loss, when air is blown through it, the pans will have to be covered, or at least a hood will have to be placed over it; even with the pans now in use, it frequently happens that, as soon as the acid becomes more concentrated, particles of acid are driven off along with the aqueous vapour, as is readily perceived by the action of the latter on the skin. When sulphuric acid is forced up by means of compressed air, and the latter allowed to blow off, after the *monte-acide* has been emptied, it will be observed that, even before all the acid has been discharged, but the stream thereof issuing from the discharge-pipe becomes less bulky and already mixed with air-bubbles, a more or less strong cloud appears at the mouth of the pipe; which cloud is readily perceived, by its action upon the skin of the face and hands, to be sulphuric acid in finely divided state, and some of it follows along with the air while blowing off after not a drop more of acid is discharged from the mouth of the pipe. When air is forced through sulphuric acid contained in covered pans, a similar effect will ensue, and the consequence will be that a large portion of the acid thus carried off in vesicular shape by the air will be lost. Supposing the air blown through the hot acid to be warmed from 0° to 100°, and to become saturated with as much water as air of the last-named temperature will bear, 1 cubic metre of such air will absorb 295 grms. of aqueous vapour, which quantity is therefore withdrawn from the acid. One cubic metre of air at 0° weighs 1·2991 kilos., and the specific heat of air is 0·2669; by the heating of 1 cubic metre of air from 0° to 100° the acid will loose—

$$1\cdot2991 \times 100 \times 0\cdot2669 = 34\cdot67 \text{ units of caloric.}$$

I now leave out of the question whether or not a larger consumption of heat takes place, owing to the fact that the water present in fluid state (in the acid) assumes the gaseous (vapour) form. In order to evaporate 1 kilo. of water we require, according to what has just been stated, $\frac{1000}{1000} = 3\cdot39$ cubic metres of air to be blown through the acid, and the withdrawal of heat (caloric) amounts, therefore, for every kilo. of water evaporated, to:—

$$34\cdot67 \times 3\cdot39 = 117\cdot53 \text{ units of caloric.}$$

By removing 1 kilo. of water from sulphuric acid at 50° B., we obtain 4.25 kilos. of sulphuric acid at 60° B., and the quantity of heat (caloric) withdrawn amounts for the kilo. of acid at 60° B. to—

$$\frac{117.53}{4.25} = 27.66 \text{ units of caloric.}$$

It cannot be said that these figures bear unfavourably upon the process under discussion, and even when more unfavourable premises are assumed, this does not alter the case. Supposing the heating of the air blown or forced through the hot acid to extend only to 50°, 1 cubic metre is saturated with 63.6 grms. of aqueous vapour, and, in order to obtain an evaporation of 1 kilo. of water, $\frac{1000}{63.6} = 15.72$ cubic metres have to be applied, which, by becoming heated to 50°, will withdraw from the hot acid:—

$$1.2991 \times 50 \times 0.2669 \times 15.72 = 27.52 \text{ units of caloric.}$$

The loss of heat for acid at 60° will, in this case, amount to 6.41 units of caloric. Stoddart intends to apply this same process, also, to obtain acid at 66° B., the only difference being that in this case the acid has to be heated to 260°. The question may be reasonably asked whether or not, at this temperature, and with so strong acid, the leaden pans will not be rapidly destroyed, and the acid so strongly contaminated with lead as thereby to become unfit for many uses.

The author of this paper does not for a moment suppose that Stoddart has not made careful researches before bringing his process into practical use at the Uphall works, but since, from the very short and incomplete notice Stoddart published in the *CHEMICAL NEWS*, no precise information about the process can be obtained as to its practical bearing, the above observations have been written with a view to obtain what, to those interested in this subject on the Continent,—and, among them, the author of these observations,—will be highly gratifying—a more complete account of Stoddart's process, with every particular relating to it.

NOTICES OF BOOKS.

A Practical Treatise on the Manufacture of Soaps. By CAMPBELL MORFIT, M.D., F.C.S., formerly Professor of Applied Chemistry in the University of Maryland. London: Trübner and Co.

SOAP-MAKING, until lately, has not advanced equally with other branches of industrial chemistry. There has been much empiricism in the methods of operation, amounting at times to so great a defect that no uniformity could be obtained even in batches of soap from the same maker. This state of things in an art so important in both its scientific and commercial bearings, naturally attracted the attention of some of our foremost chemists, and, as a consequence, are the many exquisite soaps produced during the last few years. One of the first to commence laboratory researches was the author of the work here noticed, who in 1856 introduced his system of oleic soap manufacture, subsequently substituting sal-soda fused in its water of crystallisation or the powdered sal-soda—

and semi-dehydrated sal-soda ($\text{NaO}, \text{CO}_2, 5\text{HO}$) before used, thereby reducing the salt to the necessary state of fine division without mechanical means or labour. In continuing his researches Dr. Morfit now presents to the public a handbook of soap manufacture founded on the four following principles:—

(1). The saponification of the fat acids generally, whether singly or intermixed among themselves, or with rosin, and their conversion into soap by means of alkaline carbonates, either with or without the direct use of water.

(2). The management of the water of constitution of the soap in a manner quasi-chemical, by which it is made, comparatively, a permanent ingredient.

(3). The use of carbonate of soda of different degrees of hydration, as a means of apportioning the water and alkali in the soap.

(4). The instantaneous manufacture of soap, hard and soft, without the use of caustic leys, and upon a definite plan by which the amount and composition of the product may be deduced in advance from the quantity of the materials employed.

In order to bring his work within certain limits, Dr. Morfit has confined himself to thorough instruction in the more practical bearings of the acid derivatives of neutral fats upon the manufacture of soaps, and more exclusively to the employment of crude oleic acid, olein, and fat acids generally, as soap-stock, in place of tallow, palm-oil, and similar neutral fats. This has been done to bring into commercial consideration the utilisation of the by-products of the manufacture of stearic candles, the clarification of oils, &c., these constituting an increasing source of material for which, at present, there is but a limited demand, the price being much below that of tallow. These reasons are worthy the full consideration of the soap-maker, for the market for crude oleic fats in England is never exceedingly active, and, besides, these fats cannot be utilised for illuminating and lubricating purposes, whereas there is a steadily increasing demand for tallow and the more consistent neutral fats. Dr. Morfit treats the subject very fully; the raw materials, the arrangement of the factory, the process, have each a distinct consideration. Dr. Morfit's long practical experience renders the advice detailed with respect to the best factory plant and its cost of high value, while the several apparatus are elucidated by large sectional and perspective diagrams. After the arrangement of the plant there follow numerous formulæ for the various soaps, and an estimate for the actual expense per month for working a soap-factory. Finally, there is a clearly written chapter conveying instructions in the chemical analysis of soap. Dr. Morfit advises the weighing out of 100 grains of the soap to be tested, and the solution of this quantity in alcohol, aided by the heat of a sand-bath. The solution is then to be filtered, and the alcohol of the filtrate evaporated; the filter with the residuum being heated to dryness, the constant weight, less that of the paper, expresses the percentage of foreign matters as well as of free alkali in the soap. The proportion of free alkali is determined by the quantity of normal acid liquor required to redden the blue litmus test paper; while the quantity of combined soda (NaO) is estimated from the evaporated filtrate in the same manner, the acid employed in this test serving to separate the fat element, which floats at the surface of the liquor, and may be collected in wax. As related to the manufacture of soaps, a chapter is appended on the constitution of lubricating compounds for railway and common waggon uses. The matter in all parts of the book is carefully illustrated with woodcuts, the type is large, and the arrangement admirably adapted for easy reference; the utility of the work is beyond question.

Mineral Statistics of Victoria for the year 1870. Presented to both Houses of Parliament by His Excellency's command. By authority: John Ferres, Government Printer, Melbourne.

Reports of the Mining Surveyors and Registrars; quarter ending March 31st, 1871. John Ferres, Government Printer, Melbourne.

The publications, of which the titles are above quoted, contain, as may be inferred from these titles, a very large amount of highly useful and practical information on a subject interesting, not only to those who reside in Victoria (formerly a portion of South Wales, known as Port Philip district, but erected into a separate colony by the Act 13 and 14 Vict., cap. 59), but also to the rest of the civilised inhabitants of the globe, on account of the great influence the gold production of this Colony exercises upon trade

industry and everything connected therewith or dependent thereupon. Not only are gold, silver, and diamonds* found in Victoria, but antimony, copper, coals, tin, manganese, lead, slate, and building stones, are referred to in the papers before us. From the laboratory report appended to the first-named paper—we cannot call it a blue-book because it is not dressed in the garb of that colour—and written by Dr. C. Newberry, we abstract the following particulars:—"The only novel or unusual occurrences of gold which have come under my notice during the year have been some specimens from the Empire Company's claim near Landsborough, in which gold occurs associated with native silver and copper, chloride of silver, carbonates of copper and lead, and oxide of iron in a micaceous sandstone, through which pass thin veins of ferruginous quartz; three samples of the metal obtained by the miners from this stone gave the following results in 1000 parts:—

	I.	II.	III.
Gold	197.44	517.442	189.65
Silver	755.57	460.272	768.63
Copper } ..	46.99	22.286	41.72
Lead }			
	1000.00	1000.00	1000.00

The only new compound of gold which has been received was one containing 56 per cent of gold, and 44 per cent of arsenic. The alloy was of a yellowish-grey colour, brittle, breaking with a crystalline fracture. Dr. Newberry suggested that this alloy was not a native product, but accidentally formed in a roasting kiln, but the manager of the mine where the alloy alluded to was found distinctly states that the specimen is native, as he obtained it from the quartz. Several specimens of fossil trees, fruit, leaves, seeds, and other fossil vegetable matter exhibiting organised structure have been found in a locality named Haddon, and some of these are described and illustrated with very well executed lithographs (so it reads in the original), by Dr. F. Von Mueller, Director of the Botanic Gardens, and Government Botanist at Melbourne. The Colonial Government of Victoria may be congratulated upon the excellent manner in which the reports herein alluded to are made up under its care by men evidently well up to their work.

MISCELLANEOUS.

The Bancker Collection.—For many years past there has existed in Philadelphia, and known only to those of its citizens more especially interested in scientific pursuits, a collection of philosophical and chemical apparatus unequalled in this country, and, if the opinion of foreign savans be taken, without a rival in the world. It was made and owned by the late well-known Charles N. Bancker, Esq., who devoted all the leisure hours of a life extended far beyond the average lot of man, and constantly applied to the successful prosecution of business, to the cultivation of scientific knowledge. For more than half a century he imported from the workshops of Europe their choicest productions in the way of apparatus; and his interest was not limited to one, but extended to all the sciences embraced within the scope of philosophic inquiry. In this collection will be found cabinets of minerals, with beautifully executed models in glass and wood, to exhibit the immense variety of crystalline forms; charts and maps in relief, with suites of rocks, to illustrate the geology of various countries; telescopes and instruments for observing the stars, with orreries and globes for studying the motions of the heavenly bodies; models of pumps, rams, jets, mills, and all manner of contrivances to demonstrate the properties of fluids when in rest and in

motion. The collection also contains magnets, simple and compound, with machines of the most varied description, to illustrate the phenomena of electricity and magnetism. But above all, it is rich in optical and acoustic apparatus. The Abbé Moigno, a distinguished French savant, wrote of it some years ago in *Cosmos*, that "this collection of optical instruments is certainly the most extensive and most brilliant that exists in the world. It embraces in itself more riches than all our cabinets of France, and perhaps of Europe, united. And its founder, whose zeal seems to grow with his age, does not cease to gather the freshest novelties. We exaggerate nothing when we estimate the optical treasure of Mr. Bancker at many hundred thousand francs. Besides illustrating the history of optical discovery and research during the present century, it contains numbers of the most valuable and efficient instruments, such as the saccharimeter of Duboseq, the polarising apparatus of Dove, Powel, and Soleil, microscopes by Zentmayer, Smith and Beck, &c., and complete sets of apparatus and objects for repeating the researches of Becquerel and Stokes on phosphorescence and fluorescence. Professor Henry, President of the Smithsonian Institution at Washington says in a recent letter:—"I am free to say, that, with the addition of a very few articles that have been improved or invented within the last few years, it would be the most complete series of instruments that I know of for the illustration of the phenomena and history of physics. To break up the collection and dispose of it piecemeal, would be a matter of much regret, since the value of the instruments is enhanced by the fact of their being part of a series well adapted to the illustration of the order of the development of science." Fortunately for the interest of science, the wish of Professor Henry has been, to a great extent, realised. The entire collection of optical and acoustic apparatus has been purchased by Professor Morton on behalf of the Stevens Institute of Technology, at Hoboken, and is now thrown open to all the students who may wish to prosecute researches within the walls of that great institution.—*Journal of the Franklin Institute.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 10, 1871.

This number contains the following papers relating to physico-chemical and collateral sciences:—

Action of Electricity upon the Coloured Tissues of Plants.—M. Becquerel.—This very lengthy essay contains the record of a series of experiments made by the eminent author in order to illustrate the action of electricity upon the living organism of plants.

Freezing of Water.—M. Bousingault.—After briefly referring to the experiments of the Florentine Academicians, and of Huyghens (1667), on the force exerted by the freezing of water in closed metallic vessels, the author relates a series of experiments made by him last winter in order to ascertain whether water, when put into a strong vessel (a steel cylinder of great strength, and so arranged that the dilatation, or expansion, of the water, when cooled below +4°r, could be prevented), would or would not remain liquid, even when exposed to a cold very considerably below its point of congelation, in consequence of the expansion due to the cooling down from below +4°r being prevented by the strength of the vessel containing the water and stopper (steel plug) fitted thereto. The result of this investigation was found to be that water remains liquid under the conditions alluded to, even at a temperature of -18°, but freezes instantaneously; as soon as the impediment, caused by the resistance of the plug which hermetically closes the steel vessel, was removed, free play was given

* As yet only 75 in all have been found in this country, and among this number few of great value, while a systematic search for these stones proved in 1870 a complete failure.

to the expansion of the liquid. It should be noted that the sides and bottom of the steel vessel alluded to were of such great strength as to be practically unyielding.

Sample of Incinerated Paper found among the Ruins of the recently burnt Ministry of Finance, at Paris.—E. Chevreul.—The author first exhibits to the assembly a lump of material more resembling a mineral than what it really is, the ash of paper burnt during the fire at the Ministry of Finance (purposely ignited and fired by the Communists). He next takes this opportunity to call attention to some points of the difference between the paper sized by the old and by the new process (hand-made and machine-made); the main fact being that, whereas in the hand-made and hand-sized paper the sizing (glue and alum) is only on the surface, the machine-made paper is sized in the paper mass (pulp) itself by the aid, partly of mineral, and partly of organic matter (resin and starch). These are all insoluble in water, and require, for their intimate incorporation with the pulp, that the latter be far more finely divided, to the detriment of the strength of the paper, as evidenced by the fact, for instance, that it does not stand folding without cracking and readily tearing. This, moreover, causes an essential difference in respect of the writing made on such machine-sized paper, which writing is by far more liable to be effaced, owing to not penetrating sufficiently into the mass and body of the paper. The author further observes, that upon the old-fashioned hand-made paper, sized with aluminated glue, indeleble writing may be made with indian ink, finely divided, suspended in weak hydrochloric acid (sp. gr. 1.007); whereas, for the same purpose, the machine-sized paper requires the indian ink to be mixed with very weak caustic soda solution (same sp. gr. as just alluded to).

Manner in which the Mineral Constituents of Beet-Roots are Distributed in that Vegetable.—B. Coreawinder.—The fifth portion of the exhaustive memoir "On the Chemistry of Beet-Roots,"

Method of Preparing Trichloroacetic Acid.—A. Clermont.—The main gist of this paper is, that trichloroacetic acid is readily obtained by causing hydrate of chloral to be acted upon by fuming nitric acid. The mixture, containing three times as much, by weight, of the acid as the quantity of hydrate of chloral, is first left exposed to direct sunlight for a few days, and afterwards submitted to distillation.

Dambronite and Nitrated Dambose.—P. Champion.—In the introduction to this paper, the author records, with a few words, that dambronite is a peculiar substance found recently by Aimé-Girard in the caoutchouc from Gabon, which substance is converted, by nitro-sulphuric acid, into nitrated dambronite, an explosive material; while dambose is obtained from dambronite by the action of hydriodic acid, the dambose thus prepared yielding, with nitro-sulphuric acid, also a nitrated compound, which explodes. The main portion of this essay is devoted to the description and mode of preparation of the following substances:—Bromhydric erythrite, $C_4H_8Br_2O_4$, obtained by treating erythrite in a sealed tube at 110° for a period of thirty hours along with a concentrated solution of hydrobromic acid; the body alluded to is a solid crystalline substance, insoluble in water, and fusing at 130° . Nitro-bromhydric erythrite, $C_4H_8Br_2O_4(2NO_3)$, obtained by treating the before-mentioned substance with nitro-sulphuric acid (1 part nitric, and 2 parts sulphuric acid, both concentrated); this compound is insoluble in water, fuses at 75° , is not explosive, and readily decomposed by heat. Nitro-chlorhydric erythrite, $C_4H_8Cl_2O_4(NO_3)$, a solid body, crystalline, soluble in alcohol, and fusing at 60° .

July 17, 1871.

The original papers relating to chemistry and collateral sciences contained in this number are—

Description of a Magneto-Electric Machine which produces a Continuous Current.—M. Gramme.—Illustrated by woodcuts.

Compressibility and Expansion of Gases.—M. Amagat.—The contents of this paper do not admit of any useful abstraction, owing to the fact that this would require the reproduction of a large number of tabulated results of experiments.

Existence of Nitrous Acid in Arable Soils, and on the Functions of that Acid therein.—M. Chabrier.—From this very lengthy monograph, we learn that nitrous acid is constantly present in soil, that this acid is partly converted into nitric acid, partly into other nitrogenous compounds. The average quantity of that acid found in the soil of market gardens amounts to 432 parts; corn-bearing soil, 216; orchard soil, 152; soil bearing fir-trees, 075 parts; while a soil named safrin (dried slime deposited by the river Durance) was found to contain free nitrous acid at all. It appears that the quantity and quality of the water which impregnates the soil has a great deal to do with the presence therein of the acid just alluded to.

Artificial Production of Dulcitol.—G. Bouchardat.—By treating inverted milk sugar with sodium amalgam (containing 25 per cent of sodium), the author has obtained a substance, $C_{12}H_{22}O_{12}$, solid, crystalline, not capable of fermentation, fusing at 187° , difficultly soluble in strong alcohol and in cold water. This body, therefore, appears to be identical with the dulcitol obtained from Madagascar manna, and the substance found in the juice of the *Metampyrum nemorosum*.

Fermentation and Alcoholic Ferments.—M. Dubrunfaut.

Observation on Dynamite.—P. Guyot.—The more important part of this communication is that, instead of paper, parchment is used for making the cartridges filled with dynamite (see CHEMICAL NEWS, vol. xiv., p. 21), so that no nitroglycerine can escape by soaking the paper, parchment being impervious to the liquid just alluded to.

Crystallised Aconitine.—H. Duquesnel.—This paper contains, in the first place, an exhaustive description on the best method of preparing aconitine in crystalline state for pharmaceutical purposes, and next a detailed account of the properties of the alkaloid alluded to,

Crystalline aconitine, $C_{34}H_{48}NO_6$, is nearly insoluble in water, even at 100° ; the substance is not volatile, but heated to above 130° is decomposed. Aconitine is soluble in alcohol, ether, benzene, and chloroform; insoluble in glycerine and petroleum oils. Aconitine readily forms salts with acids, and is even soluble in water impregnated with excess of carbonic acid. Although phosphoric and tannic acids, as also the double iodide of mercury and potassium, are tests for aconitine, they are not reliable unless taken in combination with its physiological effects.

July 24, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Crenic and Apocrenic Acids contained in the Mineral Waters of Forges-les-Eaux (Seine-Inférieure).—C. Bontigny.—This lengthy essay treats on the presence of proto-cerate of iron in the mineral water just alluded to, and on crenic and apocrenic acids, about which, however, nothing new is stated, the author merely drawing attention briefly to Dr. G. J. Mulder's excellent investigation on this subject. It appears that the acids alluded to are formed, in the instance of the water here mentioned, by the decomposition of organic (decaying vegetable) matter, while the iron is due in this instance to a vein of pyrites. The proto-cerate of iron is soluble in water; but that solution is instantaneously decomposed by contact with air, and hence an ochrey deposit is always found near springs, and in brooks and ditches containing the salt alluded to in solution, which salt cannot be obtained in dry pure state by any process. Crenic and apocrenic acids were first discovered by the late Berzelius in the water of Forla, Sweden.

Second Memoir on the Presence of Nitrous Acid in Mud (Slime from Rivers) and in Water employed for Irrigation.—M. Chabrier.

Researches on the Action which is Exerted by the Substances which Aid the Decomposition of Chlorate of Potassa when employed for making Oxygen.—E. Baudrimont.—The conclusions drawn from the author's researches are—(1) That chlorate of potassa is evidently an endothermic compound; (2) that the decomposition of that salt into oxygen and chloride of potassium, by the aid of certain oxides (CuO , MnO_2 , &c.), is simply due to the effect of contact; (3) that the phenomenon of incandescence, which accompanies the decomposition of this salt in the presence of the oxides alluded to, is due to the sudden expulsion of the caloric of formation (*calorique de formation*) of that salt; (4) that chlorate of potassa, while in contact with the oxides of copper or manganese, possesses the property of becoming liquefied below its ordinary melting-point.

Quantity of Caloric Set Free during the Formation of Organic Nitrated Compounds.—Dr. Berthelot.—This exhaustive memoir treats on nine different compounds, viz.:—Nitric ether, nitro-glycerine, nitro-mannite, gun-cotton, xyloidine, nitro-benzene, binitro-benzene, chloro-nitrated benzene, nitro-benzoic acid. The investigation of the author has been mainly directed to ascertain the amount of caloric set free during the formation of these substances.

Fermentation and Alcoholic Ferments.—M. Dubrunfaut.

New Theory of Fermentation.—A. Petit.—The contents of these papers, however valuable in a scientific point of view, are not suited for useful abstraction.

Estimation of Free Hydrofluoric Acid.—P. Guyot.—The author proposes to apply, for this purpose alluded to, the reaction between fluoride of potassium and sesquichloride of iron, yielding a white-coloured precipitate of sesqui-fluo-ferrate of potassa, Fe_2Cl_3KFI , the reaction taking place according to the following formula:—

The liquid, which contains free hydrofluoric acid, is first exactly neutralised with pure carbonate of potassa, and next, after filtration, a titrated solution of perchloride of iron is added.

This number contains also several important meteorological, astronomical, and physico-geographical papers and essays.

Les Mondes, July 20, 1871.

This number contains the two following original papers relating to physico-chemical sciences, but, both being accompanied by woodcuts absolutely required for the proper understanding of the subject, we only quote the titles:—

Magneto-Electric Machine which Produces Continuous Currents.—M. Gramme.

Support with Total Reflection for the Projection of Moving Images.—J. Duboscq.

A large number of pages of this number are devoted to a subject of public and political economy on—

Taxation by One Single Impost.—C. Tellier.—Which certainly deserves the serious study of political economists and others, the main and very important points being that the author's proposals tend to create the most simple, most productive, and most equitable tax.

Moniteur Scientifique, Nos. 349 and 350 (double number), July 1 and 15, 1871.

This number contains the following original matter relating to chemistry and allied sciences:—

Processes for Detecting, Distinguishing, and Separating from each other Silk, Wool, and Vegetable Fibres in Mixed Woven Fabrics.—Dr. E. Kopp.—This lengthy memoir contains, in

a condensed form, all the information on this subject found dispersed in various published works, including, also, the various methods employed on the large scale for separating animal and vegetable fibres from each other when they occur in mixed fabrics. From the contents of this paper we cannot make any general abstract; but among some of the particular reactions we find the following for detecting wool in silk, and *vice versa*, based upon the fact that wool contains sulphur, while silk does not. The tissue to be tested—it should be, however, white, not dyed—is put into a solution of caustic potassa or soda, wherein, previously, oxide of lead has been dissolved; woollen fibres become black when immersed in this liquor, whereas silk remains unchanged. Another test for the same purpose is ordinary nitric acid, which dissolves silk in the cold, but hardly affects wool.

Changes which the Progress of Modern Chemistry has wrought in Therapeutics and Hygiene.—F. Papillon.—This exhaustive monograph is divided into the following chapters:—General action of medicaments upon the human system; alkaloids; anæsthetics; disinfectants, antiseptics, antismiasatics; phenic acid; iodine, bromine, and compounds thereof; acids and mineral salts; artificial essences.

The American Journal of Science and Arts, July, 1871.

This number contains the following original papers and memoirs:—

Some Phenomena of Binocular Vision.—J. Le Conte.—The continuation and fifth part of the author's essay on this subject. This portion, copiously illustrated with woodcuts, treats on stereoscopic phenomena.

Three Masses of Meteoric Iron from Augusta County, Virginia.—J. W. Mallet.—The author describes, and illustrates by means of woodcuts, three specimens of meteoric iron found in the county above named. The sp. gr. at 15° of these samples was respectively found to be 7.853, 7.855, and 7.839. The composition of the substances was ascertained to be, in 100 parts, the following:—Iron, 88.706, 88.365, 89.007; nickel, 10.163, 10.242, 9.964; cobalt, 0.396, 0.428, 0.387; copper, 0.003, 0.004, 0.003; tin, 0.002, 0.002, 0.003; manganese, a trace in two out of the three samples; phosphorus, 0.341, 0.362, 0.375; sulphur, 0.019, 0.008, 0.026; chlorine, 0.003, 0.002, 0.004; carbon, 0.172, 0.185, 0.122; silica, 0.067, 0.061, 0.056;—totals, 99.872, 99.659, 99.947. The chlorine, the author states, is not an essential constituent of the original masses, but has been derived from the soil in which the iron has lain imbedded.

Application of Photography to the Determination of Astronomical Data.—A. Hall.—An important astronomical-physical essay.

Ralstonite, a New Fluoride from Arksut-Fiord, Greenland.—G. J. Brush.—The mineral is colourless to white, with a vitreous lustre, crystalline in octahedra; hardness equal to about 4.5; sp. gr., 2.4. When heated in a test-tube, the mineral whitens, yields water at first, then gives off fumes and a copious white sublimate, while the walls of the tube are etched; the vapour in the tube, as well as the water, exhibit an acid reaction. Heated before blowpipe-flame, the mineral whitens without fusion, and colours the flame a soda-yellow; heated with cobalt solution, a bright alumina blue appears. In salt of phosphorus the substance was readily dissolved, giving a colourless head. The mineral was, on examination with a magnifier, found to be so intimately associated with thomsonolite, that it was deemed impracticable to separate a sufficient quantity for anything more than a preliminary qualitative investigation in the wet way, which led to the result that the mineral is essentially a hydrous fluoride of aluminum, with probably a small amount of calcium and sodium. Its isometric form and its infusibility distinguish it from all other fluorides yet described as occurring at the cryolite locality in Greenland. The only mineral which, in general chemical characters, approaches it is the fluellite from Stenna-Gwyo, in Cornwall, a rare mineral which, according to Wollaston, is a fluoride of aluminum.

Atomic Weights of Cobalt and Nickel.—R. H. Lee.—Reserved for complete reproduction, an observation also applicable to the following paper.

Note on the Spectrum of the Corona.—C. A. Young.

Jahrbuch der Kaiserlich-Königlichen (Austro-Hungarian) Geologischen Reichsanstalt, No. 1, 1871.

In addition to a large number of strictly geological papers and memoirs, this number contains—

In Memory of Wilhelm Haidinger.—F. Ritter von Hauer.—An excellent biography of the lately deceased celebrated *savant* just named.

Studies on the Saline Region of Siebenbürgen (Transylvania).—F. Posepny.—The second section of a lengthy memoir containing a very large number of results of chemical analysis of the water of saline springs, and of the produce of various layers and deposits of rock-salt and of various mineral waters met with in the country alluded to.

Polytechnisches Journal von Dingler, second number for June, 1871.

The original papers and memoirs relating to chemistry and collateral sciences are the following:—

Analysis of a Sample of Universal Manure (Universal Dünger).—Dr. H. Vohl.—Under this name, the firm Hirsch, at Enderrich, near Bonn, has for some years sold an artificial manure which exhibits a yellowish-grey colour, is acid to test-paper, does not give off any strong smell, and is composed, in 100 parts, of—Water,

14.714; residue left after ignition, 58.593; loss by ignition, 26.808; nitrogen, 6.407; total phosphoric acid, 17.185; of this quantity, 6.188 is readily soluble, and 10.995 described as difficultly soluble; sulphate of potassa, 8.456.

Note-Paper which Contains Arsenic.—Dr. H. Vohl.—The author calls attention to the fact that there is now in the trade, at least on the Continent, a kind of beautifully light and deep rose-coloured note-paper, which, on being exposed to sunlight, is readily bleached, and, on being further investigated by the author, was found to be coloured with the arsenical residues of the fuchsin manufacture, and to yield, when treated with Marsb's apparatus, a considerable arsenical deposit.

Results of the Application of Various Kinds of Manure to Beet-Roots.—Dr. O. Tech.—This paper contains, in tabulated form, the results obtained on the large scale by the use of various kinds (23 in all) of manures, as applied to beet-roots in Bohemia.

Beet-Root Sugar Industry in Europe.—Dr. Dingler.—At the end of last year, there existed in Europe 1507 beet-root sugar works, of which 483 belong to France, 310 to the German Confederation, 263 to Russia, 228 to Austro-Hungary, 153 to Belgium, 42 to Poland, 20 to the Netherlands, 4 to Sweden, and 1 each to Italy and the United Kingdom of Great Britain and Ireland.

First number for July, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Stoddart's Suggestion Concerning the Concentration of Sulphuric Acid by Blowing Air through the Fluid while Hot.—F. Bode.—Inserted *in extenso*.

Application of Sodium as an Explosive Agent.—F. Springmühl.—The contents of this paper, illustrated with several woodcuts, describe a series of experiments made with the view to ascertain how far, and under what conditions, sodium may be applied as a substance suited to cause, by contact either with water or other materials, the explosion of vessels wherein these substances are contained. The force exerted is by no means small, as may be inferred from the following:—46 grms. of sodium and 18 grms. of water yield 2 grms. of hydrogen, a bulk of 2247.19 cubic centimetres. The space required for the sodium only amounts to 447 c.c. (the water is contained, previous to its coming into contact with the sodium, in a small bulb, which is solidly fixed by means of a neck to the bulb wherein the sodium is contained, which latter may be made of 50 c.c. capacity), taking 50 c.c. for the capacity of the explosion bulb, the pressure of the gas generated inside will be 450 atmospheres, equal to 6800 lbs. to the square inch.

Preparation and Use of Manganates and Permanganates of Alkalies.—E. Desclabissac.—This paper contains a description of the best and most practical methods suited for the manufacture of the salts alluded to, on the large scale.

Sulphuret of Cadmium (So-Called Cadmium Yellow), as a Pigment for Imparting a Yellow Colour to Toilet Soaps.—E. Schering.—The author, a manufacturing chemist, at Berlin, states that the pigment alluded to has been found to be the most durable and least expensive to impart to toilet soaps a fine yellow hue. The sulphuret is first rubbed up with some oil, and this mixture well incorporated by stirring with hot and liquid soap mass; the pigment does not dissolve therein, but is only finely divided. Two varieties of the cadmium yellow are now prepared on the large scale, one having a lemon, the other an orange-yellow colour.

Composition of Argol.—J. C. Sticht.—The author gives, in a tabulated form, the results of the analysis of 15 different samples, obtained from various wine-growing countries, of argol (crude bitartrate of potassa). The quantity of the salt was found to vary, in these samples, from 90 per cent to 34 per cent, while the quantity of tartrate of lime present in these samples varied from 52 per cent to 4 per cent.

NOTES AND QUERIES.

Distillation of Wood.—J. H. Mayor will find all the required information in a work entitled "Die Trockene Destillation der Holzes und die Verarbeitung der Durch Daseibee Erhaltenen Roh Producte," von Dr. Ed. Asamusa (Berlin: 67, Verlag von T. Springa).—V. C.

Distillation of Wood.—(Reply to J. H. Mayor).—We do not know of any book specially treating on this subject, but useful information will be found in vol. xviii. of the CHEMICAL NEWS, pages 91, 105, 132, and 168. You can also refer to vol. i., part 1, p. 340 and following, of the "Chemical Technology" of Richardson and Ronalds.

Schio Liao.—I have read an account lately of a cement used in China called *schio liao*, which is composed of 3 parts of blood and 4 parts of slaked lime, the blood to be beaten to deprive it of fibrine. Will you kindly say what is the meaning of destroying the fibrine, and in what way I am to proceed?—E. J. L.

NOTICE TO AMERICAN SUBSCRIBERS.

THE CHEMICAL NEWS.

VOL. XXIV. No. 613.

NOTE ON THE ACTION OF ALDEHYDE ON THE TWO PRIMARY UREAS.*

By Dr. J. EMERSON REYNOLDS.

THE action of the dicarbon aldehyde of the fatty series, C_2H_4O , on certain derivatives of ammonia, has of late been studied with considerable care, and most interesting results arrived at in the course of the investigation. We have been long familiar with the reactions of aldehyde with aniline, described by Schiff, who has shown that the dyad group C_2H_4'' , or ethylenidene, as it is often called, can replace successively two distinct proportions of hydrogen in the double molecule of aniline, water being eliminated according to the equations:—

We are also acquainted with analogous reactions which have been obtained with amides and aldehydes of the aromatic series; it therefore appeared to be a matter of some interest to examine the action of aldehyde on another class of ammonia derivatives. I refer to the group of so-called *ureas*. Of these, there are at least two primary bodies,—one the well-known product of the animal organism, or Wöhler's beautiful artificial urea; and the other, the sulpho-urea which I discovered a few years ago.

It is unnecessary now to discuss the question of the identity or otherwise of Wöhler's and the normal urea. It is sufficient here to mention that all my experiments have been made on Wöhler's urea and on the analogous sulphur compound.

It will be convenient for the present to regard the two ureas just referred to as ammonia derivatives respectively of carbonic (according to Dr. Kolbe, carbamic), and sulpho-carbonic acids. Thus—

My object being to attempt the partial or complete replacement of hydrogen in each urea by the ethylenidene group, according to the equation

I may now be allowed very briefly to state the chief results arrived at in the course of the inquiry.

Action of Aldehyde on the Sulpho-Urea.

The first experiments were made with the sulpho-urea. A quantity of the pure compound was dissolved to saturation in nearly anhydrous aldehyde. The hot saturated solution was digested in a hermetically sealed flask, at a temperature of $100^\circ C$, for two hours. The solution was then allowed to cool. No urea crystals were deposited. After two days' standing, however, a number of minute, spherical, sub-crystalline masses were found to have attached themselves to the sides of the flask, and these gradually increased in quantity, until a considerable amount had been obtained. The clear liquid gave a

copious white precipitate with water and with alcohol. The deposited body was carefully washed with cold alcohol, in which it is very slightly soluble, and then purified by solution in a large volume of boiling anhydrous alcohol, from which the new body separates out to a large extent on cooling a somewhat starch-like granular substance, seen under the microscope to be made up of extremely minute crystals. The analysis of the body gave numbers agreeing well with the formula:—

and is, therefore, derived from the urea by the replacement of half the hydrogen by ethylenidene.

The new body is but slightly soluble in ether, rather more so in cold alcohol, but its solubility in boiling alcohol is much greater. In consequence of its relations to these solvents, the substance can be easily purified. It is but very slightly, if at all, truly soluble in cold water; but when digested at $100^\circ C$. with water, solution is obtained,—but solution in consequence of decomposition,—aldehyde being produced, and the urea separated with some ammonium sulphocyanate. The essential reaction is probably correctly represented by the equation—

or the converse of that, according to which the *ethylenidene-sulpho-urea* is formed, dilute acids and alkalis act in the same way.

From the alcoholic solution I have obtained a platinum salt and a gold compound.

Action of Aldehyde on Wöhler's Urea.

The urea was dissolved nearly to saturation in aldehyde, and the solution digested in a sealed flask for two hours at $100^\circ C$. When cool, the flask was opened, and the contents poured into a suitable vessel, and the aldehyde slowly evaporated. No crystals of the urea were deposited, but a transparent pasty mass remained when the solvent had been almost wholly driven off. After standing for twenty-four hours, the residue was found to be white and friable. The mass was powdered, and digested in the cold with weakly-anhydrous alcohol, in which it is very slightly soluble at ordinary temperature, washed with the same liquid, and then boiled with alcohol. The filtered solution so obtained deposits, on rapid cooling, a considerable quantity of a flocculent body, seen under the microscope to be wholly made up of minute and considerably modified monoclinic crystals. Analysis gave the formula:—

for this body. A platinum compound has been obtained, but no gold salt.

The new substance is easily decomposed by digestion with water into aldehyde, and the products of decomposition of the urea. The first stage of the reaction, may, no doubt, be represented by the equation:—

Having succeeded in replacing half the hydrogen in each of these ureas, directly, and by a very simple reaction, I endeavoured to go a step farther, and substitute a hydrocarbon group for the residual hydrogen within the molecule. All attempts in this direction have hitherto been fruitless.

In view of the facts above-stated and others well known, proving that half the hydrogen only is capable of replacement, and that each atom of nitrogen within the molecule of the urea is somewhat differently engaged, we are clearly warranted in slightly modifying the rational formula of each urea, in order to bring it into more complete harmony with the facts. The extent of the alteration is apparent,

* Read before the British Association, Edinburgh Meeting, Section B.

when we write the formulæ of the ethylen-ureas referred to in this note, thus:—

ON THE CONSTITUTION OF SALTS.*

By J. ALFRED WANKLYN,

Corresponding Member of the Royal Bavarian Academy of Sciences.

SOME time ago I made the observation that there existed a numerous class of chemical compounds isomeric with the soda-salts of the fatty acids, but radically different from them in constitution. The compound obtained by the action of acetic ether on ethylate of soda belongs to this class. Its composition is expressed by the empirical formula $\text{C}_4\text{H}_7\text{NaO}_2$, being an isomer of butyrate of soda; but instead of yielding butyric acid when treated with dilute sulphuric acid, it gives alcohol and acetic acid, showing that its four atoms of carbon are not bound together in one group. At first sight two theories of the structure of this singular compound present themselves. It might be acetate of sodinated-ethyl or sod-acetate of ethyl—

But the action of iodide of ethyl on it demonstrates that it is neither the one nor the other. Treated with iodide of ethyl it gives neither acetate of butyl nor butyrate of ethyl. Instead of yielding either of these products it breaks up into alcohol, isocaproate of acetylated ethyl, and iodide of sodium, thus:—

The mechanism of this reaction I have explained on former occasions. The fact to which I wish to call particular attention is, that herein we have an example of ethyl being substituted for sodium, without true replacement being effected. It is a critical instance showing that monatomic ethyl does not discharge the function of the metal sodium. As those who are familiar with my work will recollect, I assign to the isomer of butyrate of soda the rational formula—

and the name acetate of ethylene-sodium.

Reasoning from this sodium compound and from the multitude of double sodium-salts which are known to exist, I have been led to assign a triatomic function to the metal sodium, and formulate such compounds as caustic soda and acetate of soda as follows:—

Should these views prevail (and the more I enquire into the subject the more disposed I become towards them), most of the common formulæ of metallic compounds will be altered. The water-type, which is at the present moment employed to represent metallic salts, will, in many instances, have to give way to the ammonia-type; and so the metallic salt and the corresponding acid will be represented by chemical formulæ radically dissimilar.

One of the consequences of the new theory being, thus, that metallic salts and acids are radically unlike, it derives support from experimental differences between salts and their corresponding acids.

The salts of alumina are usually regarded as approximating most closely to the "so-called salts of hydrogen." The recognition of fundamental differences between salts of alumina and acids is, therefore, specially to the point. I have recently observed two such differences. Nitrate of alumina, unlike the so-called nitrate of hydrogen, does not dissolve chromate of silver. A mixture of nitrate of alumina with hydrochlorate of alumina in aqueous solution admits of being boiled without evolving chlorine.

These experimental facts exhibit striking difference between the salt and the acid. They also show that salts of alumina are not so prone to decomposition as is commonly believed.

ON THE EFFECTS OF HEAT ON PROTOPLASMIC LIFE, PREVIOUSLY DRIED.

By F. GRACE CALVERT, F.R.S., &c.

THE following series of experiments was instituted as a sequel to those already published, and with the view of ascertaining whether animalculæ which had been previously dried would resist a higher temperature without being destroyed than animalculæ when heated with the fluid in which they were living.

In hope of throwing some light on this point, small thin slips of glass, 3 centimetres in length and 5 m.m. in breadth, were taken, and one side of each slip was smeared with a thin coating of putrid albumen containing a considerable quantity of microscopic life.

Fifty-six of these slips of glass were prepared on the 5th of July, 1871, and allowed to dry in the air for twenty-four hours, when twenty-eight of them were taken and sealed in tubes of the same size as those used in the experiments already published, whilst the remaining twenty-eight were placed in an air-bath, and kept at a temperature ranging between 100° and 120° F. for fourteen hours, and then sealed in tubes.

Therefore there are two series of experiments—one in which the putrid fluid was merely dried on the slips at natural temperature; the other in which the fluid, after being dried in the air, was thoroughly desiccated in the bath.

Four from each series were set apart and not heated; the remaining tubes of both of the series were rolled in wire gauze to prevent, as far as possible, any danger arising from the accidental bursting of any of the tubes, and placed in an oil-bath, which was gradually heated and kept for half an hour at the following temperatures:— 100° , 200° , 300° , 400° , 500° , and 600° F. Four tubes from each series were taken out at each temperature, and those that remained were kept in the bath with its temperature at another fixed point for half an hour.

The above experiments gave rise to three series of experiments:—

First.—Some of the glass tubes were broken; the small slips of glass they contained were taken out and laid on a microscopical slide, which had previously been moistened by a drop of pure distilled water, left for about fifteen minutes, and then examined.—July 8.

Second.—Other slips were taken from each of the series and placed in small tubes, 5 centimetres in length and 8 m.m. internal diameter, with equal quantities of pure distilled water, and then hermetically sealed.

These slips were heated on the 11th of July, and examined on the 15th.

Third.—Slips were placed in tubes, 7 centimetres in length and 15 m.m. in diameter. The tubes were then filled with a solution of albumen which had been prepared on the 22nd of April last, and was still absolutely free from life, having been prepared by the process described in my first paper.

This series was commenced on the 11th and examined on the 15th of July.

* Read before the British Association, Edinburgh Meeting, Section B.

Series I.—Slips (*dried in air*) and simply heated at the various temperatures. Moistened with water on the slide of the microscope, and examined immediately.

Not heated.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. Six or seven living animalculæ were present under each field. None were swimming, but all were moving to and fro with distinct vital motions. The majority are ordinary vibrios; a few of them, however, are long vibrios.	2. Life is present to about the same extent, and with about the same vitality, as exists in 1.	3. Same class of vibrios exist here as in 1 and 2, and to about the same extent and with the same amount of vitality. So that up to this point there appears to be little or no difference in the amount of life.	4. There is a very decided decrease in the amount of life here. All the long and nearly all the ordinary vibrios have been destroyed. Two or three small vibrios are still present, however, moving to and fro under each field.	5. No life present.	6. No life present. The albumen on the glass-slip has been charred, and pieces of this charred mass appear under the microscope to resemble shellac.	7. No life present. The albumen on the slip is charred to a greater extent than 6, and small carbonised pieces, mixed with the shellac ones, were present.

Series II.—Slips (*dried in bath for fourteen hours between 100° and 120° F.*) were simply heated at the various temperatures. Moistened with water on the slide of the microscope, and examined immediately afterwards.

Dried in bath, but not heated after.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. There are seven or eight animalculæ under each field. They are principally ordinary vibrios, and there were also a few long and very long vibrios present.	2. Exactly the same class of life is present here as in 1. It exists to the same extent, and with the same amount of vitality.	3. There is no difference in the life present here to that existing in 1 or 2.	4. There is a very decided decrease in the amount of life present here to that observed in 1, 2, or 3. All the ordinary, long, and very long vibrios have been destroyed, and only a few small black vibrios are left, which are sufficiently distinct in their appearance and motion to show that they are still alive.	5. All the life has been destroyed.	6. No life present.	7. No life present.

Series III.—Slips (*dried in the air*), and afterwards heated to the different temperatures, were introduced into small tubes containing pure distilled water on the 11th of July, hermetically sealed, and on the 15th of July the water in each of the tubes was examined.

Water alone for comparison.	Not heated at all.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No animalculæ life present.	2. Four or five ordinary vibrios are present in the whole drop, two of which are swimming about.	3. About forty bacteria vibrios are sprinkled about under each of the bottom fields, and about ten or twelve long and ordinary vibrios are swimming about throughout the drop.	4. One or two large or ordinary vibrio is observed under most of the field moving to and fro.	5. A few energetically-moving dots and small vibrios are present throughout the whole drop. No bacteria.	6. No trace of animalculæ life is present, but a number of pieces of matter are oscillating to and fro.	7. No animalculæ life present.	8. No animalculæ life present.

Series IV.—Slips (dried in bath at 100° and 120° F.), afterwards heated to the different temperatures, and the slips then taken from their original tubes and introduced into tubes containing pure distilled water on the 11th of July, and examined on the 15th.

Merely dried in bath, not heated.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. About one ordinary vibrio was observed moving to and fro under each field.	2. The appearance of the fluid here is exactly the same as 1.	3. About seven or eight bacteria vibrios are present under each field, and one ordinary swimming vibrio is present under most of the fields.	4. About one or two ordinary swimming vibrios were observed throughout the whole drop.	5. No animalculæ life present.	6. No animalculæ life present.	7. No animalculæ life present.

Series V.—Slips (dried in air), afterwards heated to the different temperatures, were then introduced into tubes containing equal quantities of an albumen solution. They were hermetically sealed on the 11th of July, and examined on the 15th.

Albumen alone for comparison.	Not heated at all.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No distinct vibrio life is present.	2. Four or five distinct vibrios were observed moving to and fro throughout each drop. No bacteria vibrios were observed.	3. Four or five bacteria vibrios were present at the bottom of each field, and one or two ordinary or long vibrios were swimming about above them.	4. About one ordinary vibrio moving to and fro under most of the fields, and one or two bacteria vibrios were observed throughout the drop; but no swimming life is present.	5. A few bacteria vibrios were present throughout the drop, and a very few were moving to and fro.	6. No life.	7. No life.	8. No life.

Series VI.—Slips (dried in bath between the temperature of 100° and 120° F.) heated to the different temperatures, and introduced into the tubes containing albumen solution, and sealed on the 11th of July and examined on the 15th.

Albumen alone for comparison.	Not heated at all.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No distinct vibrio life present.	2. About ten or twelve ordinary bacteria vibrios are present at the bottom of each field, and twelve or fourteen ordinary and rather long vibrios are swimming. There is also a number of some fungi present, which gives the fluid a turbid appearance when shaken up.	3. There is about the same amount of life here, and the fluid has much the same appearance as 2.	4. There is life present here, but not to such an extent as it exists in either 2 or 3.	5. A few bacteria vibrios are present at the bottom part of each field, and one or two ordinary vibrios and microzymes are swimming about above them.	6. No life.	7. No life.	8. No life.

ON THE USES OF A NEW PRECIPITATING REAGENT OF COPPER.

By HUGO TAMM.

IN the current work of analytical chemistry the use of apparatus is to be avoided on nearly every ground; and, on the contrary, reagents ought to be employed whenever this can be done with safety. But a reagent, to be perfect, must fulfil certain conditions.

(1). When employed for the determination of a solid substance it should be volatile, or, if it is fixed, it should not form, with the precipitate, compounds of indefinite composition.

(2). It should form, with the element to be determined, a compound as insoluble as possible.

(3). It should not introduce in the liquid separated from the precipitate any substance likely to alter the behaviour of its constituents, with general or respective reagents, and, least of all, it should not introduce any substance difficult of separation from any of the constituents.

(4). It should separate the element to be determined, in the shape of a compact precipitate, in neutral or acid liquors, and allow the other elements of the combination to remain in solution.

This is, perhaps, the most important principle in analytical chemistry.

The reagent which I now propose fulfils these conditions, and is, consequently, very perfect; in practice it will be found very useful. It is obtained by dissolving in distilled water equal weights of sulphocyanide of ammonium and of bisulphite of ammonia. This mixture keeps well, and can be used several months after its preparation, providing it is not left exposed to the air for any length of time; but, should a slight alteration take place in its composition, this would be of no consequence.

A mixture of equal weights of sulphocyanide of potassium and of bisulphite of potash or of soda answers equally well; in fact, it keeps still better than the former mixture, and the only objection to its use is its being composed of fixed salts.

Either of the five salts above mentioned can be obtained in a great state of purity, and, as both mixtures are equally perfect as regards the estimation of copper, I should recommend the first for analytical purposes and the second for simple assays of copper.

The important property of this reagent consists in forming, in solutions of copper acidulated with hydrochloric acid, an abundant white precipitate of subsulphocyanide of copper, which is completely insoluble.

The only precaution to take to ascertain the presence of copper in a solution is to neutralise any nitric acid which might be present with an excess of ammonia, and then to acidulate the solution with a slight excess of hydrochloric acid.

The behaviour of this reagent is easily explained. Bisulphite of ammonia, which, in ordinary circumstances, reduces but very slowly proto-salts of copper, reduces them instantaneously, in presence of sulphocyanide of ammonium, and this salt forms immediately with the subsalt of copper produced the subsulphocyanide of copper, which is precipitated, and thus the behaviour or the mixture is that of an ordinary simple reagent.

The qualitative uses of this reagent are somewhat limited; still it is most useful to ascertain at once beyond a doubt that a blue ammoniacal liquor owes its colour to copper. For this purpose the ammoniacal liquor is supersaturated with hydrochloric acid, a few drops of the reagent are added, and, if copper is present, it is immediately precipitated. If, on the contrary, the blue colour is due to nickel or iridium, no precipitation takes place, but if the colour is partly due to copper and partly to some other metal, then a separation takes place, copper is precipitated, and the filtrated liquor, saturated anew with ammonia, assumes a blue tinge.

It is needless to say that if, through neglect or through some unexpected reaction, a white precipitate were obtained with the reagent, and if some doubt existed as to its containing copper, it would only be necessary to oxidise and dissolve the precipitate in nitric acid, and saturate the solution with ammonia in excess to obtain—copper being present—the characteristic blue liquor. Or the white precipitate may be dissolved at once in ammonia. In presence of the air it oxidises rapidly, and soon imparts to ammonia the blue colour due to copper.

When the white precipitate of subsulphocyanide of copper is thoroughly washed—and this is the case, not as might be presumed when the washings are free from sulphocyanides as detected by perchloride of iron; but, on the contrary, when they are free from chlorides which adhere more strongly to the precipitate than sulphocyanides—and when the precipitate is thoroughly dried, its formula is Cu_2CyS_2 , and it contains 52.30 per cent of copper.

As in chloride solutions the only metal precipitated by the reagent is copper, it affords easy means of separating this metal from all others, and of estimating it with promptitude, and with the greatest accuracy. In analytical researches and in quantitative determinations it is an invaluable reagent.

In the few examples which follow will be found the way of proceeding and the precautions to take to effect the separation and determination of copper, in the chief products containing this metal.

Estimation of Copper in Pure Copper and in Swedish and Russian Copper.

Twenty grains of the metal are dissolved in nitric acid. The solution, diluted with water, is supersaturated by ammonia, and a sufficient quantity of hydrochloric acid is added to make the blue colour disappear and to give a greenish solution quite clear. The liquor, which is very warm, is allowed to cool to a temperature of about 50°C ., and enough water is added to make it occupy from $\frac{1}{4}$ to $\frac{1}{2}$ of a pint. The reagent is then added little by little. At first a dark brown liquor is obtained which rapidly turns to a white precipitate* which settles rapidly. When the precipitation is complete, a few drops of the reagent are added in excess; the whole is allowed to rest in a warm place for some little time. The precipitate is collected on a double filter, and washed until no chlorine can be detected in the washings by means of nitrate of silver. It is then thoroughly dried, and afterwards weighed, and the quantity of copper is calculated from the composition of the precipitate given above. The drying of the precipitate being the longest part of the operation, whenever it is required to make a rapid determination the process can be modified as follows:—

The washed sulphocyanide of copper is detached while wet from the filter; the filter is burnt, and its ashes are mixed with the precipitate, which is digested for some time with an excess of sulphide of ammonium. By this means sulphuret of copper is obtained. It is filtered and thoroughly washed; it is then dried very rapidly in a small porcelain crucible, and calcined. This being done, a little excess of pure flour of sulphur is thrown in the crucible, which is then carefully covered, and all the sulphur is driven off at a low red heat. After cooling the residue of sulphuret of copper presents the constant formula Cu_2S , and it contains exactly $\frac{1}{2}$ of its weight of copper.

Estimation of Copper in Bar Copper, and in Native Copper.

The complete analysis of this metal is very delicate, and it can safely be assumed that no analysis of it, previous to the use of sulphocyanides, was ever very perfect, or very reliable. On the contrary, by using the reagent every

* If the dark colour persisted, and if nitrous fumes were evolved the solution should be rejected at once as unfit for use. This happens when nitric acid has not been properly saturated.

trace of foreign metals can be easily detected and determined after the separation of copper is effected.

Twenty grains of the metal are dissolved in nitric acid, and, if the solution is quite clear, the copper is estimated exactly as in the former example. If, on the contrary, a precipitate of oxides of antimony or tin is manifest in the liquor, it should be dissolved by adding a little hydrochloric acid, or a fresh lot of metal should be dissolved in aqua regia. This being done, the determination of copper is proceeded with exactly as previously stated.

For the complete analysis, 100 grs. are dissolved in nitric acid or in aqua regia. The solution, supersaturated with ammonia, is re-acidulated with a slight excess of hydrochloric acid, and the liquid is made to occupy at least one pint. The reagent is then added, with the precaution already indicated, and in general, when the precipitation is complete, the supernatant liquid assumes a pink or red colour due to sulphocyanide of iron. The liquid is then filtered on a double filter (this precaution is useful because the sulphocyanide of copper is apt to pass through single filters), and the precipitate is well washed. The liquid, mixed with a little more hydrochloric acid, is boiled until no smell of sulphurous acid from the reagent can be detected; it is then submitted to analysis.

Lead, arsenic, and antimony will generally be found. Even coppers leaving no residue in nitric acid contain antimony which can be detected and estimated when separated in this way. The same remark applies to tin, which exists more often than might be supposed. Bismuth, nickel, and zinc are three metals which exist very frequently, also, in copper. Cobalt is found pretty often too, and silver and iron are nearly always present.

Sulphur, which exists frequently, must be determined in a special operation.

The usual method of analysing copper, by precipitating it with sulphuretted hydrogen, and by treating the precipitate with sulphide of ammonium, is most imperfect. The bulky precipitate of sulphide of copper holds the small quantities of sulphurets of antimony, arsenic, and tin, with an adhesive power nearly equal to the dissolving power of ammonia. If the dissolving power of this reagent is increased by addition of sulphur, a large proportion of copper is dissolved, and the analysis is complicated and inaccurate. Furthermore, the separation of the small quantities of the other metals precipitated with the copper is also difficult and imperfect by ordinary processes.

Estimation of Copper in Brass, in Bronze, and in German Silver.

The separation of copper in alloys containing considerable quantities of zinc presents great uncertainty when effected by means of sulphuretted hydrogen. This is due to the capricious behaviour of the zinc in presence of sulphuretted copper, and this process ought to be rejected without hesitation, the more so that the reagent answers admirably the purpose, and that the separation effected by its means is one of the neatest in analytical chemistry.

Quantities of the alloys, varying from 20 to 50 grs., should be dissolved for the determination of their chief constituents, and no less than 100 grs. should be employed for the determination of the smaller quantities of foreign metals. The proceedings are identical with those indicated in former examples.

In bronzes, tin can be separated by nitric acid. This mode of separation is sufficiently accurate for ordinary purposes, but in correct analyses it would be advisable to dissolve the alloy in aqua regia, and proceed first to the separation of copper.

With these alloys the copper reagent proves invaluable, not only as affording means of estimating with facility and accuracy the composition of important alloys, but also as enabling the chemist to determine the very important question of the cause or causes of brittleness in those alloys.

Estimation of Copper in Pyrites, in Copper Ores Generally, and in Slags.

The reagent proves much less useful and necessary in the analyses of these minerals and slags than in those of the former products, for the reason that ordinary methods answer well when applied to them. Indeed, it is not advisable to use the reagent at first to effect the separation of copper, unless this metal exists in large quantity, and is alone to be determined. However, if uniformity in the estimation of copper was an object, no objections would be raised against using the reagents which separate the copper with equal perfection whatever substances accompany it. But for analytical purposes it would be best to precipitate by sulphuretted hydrogen, copper, and the group of metals which are precipitated with it, and thus to separate them from the large proportions of iron and of earthy matters which may be present.

The precipitated sulphurets being re-dissolved in nitric acid or in aqua regia, this solution can be submitted to analysis, and, in most cases the reagent can be employed with advantage in this part of the operation, and if copper is the most abundant metal of all, it will prove as useful as ever. If, on the contrary, copper formed only a small fraction it would be best not to use the reagent at all, but to apply the ordinary methods of separation.

Some pyrites and certain earthy minerals contain about equal proportions of bismuth and copper. In these instances it is best to separate bismuth first, to avoid all possibility of this metal being precipitated by water and mixed up with copper. The same remark applies to cases where antimony is present in large proportions.

As a general rule, when a metal, such as lead, silver, antimony, or bismuth, exists in large proportions, and when this metal can be easily separated from copper, it is best and safest to effect its separation at once.

There are instances in which the separation of copper is not only difficult but imperfect with ordinary methods. Such is the case when copper exists in a liquor with palladium, vanadium, molybdenum, and cadmium. In these instances no better means of separation can be resorted to than to use the reagent, which effects all these separations as, indeed, most separations with the greatest perfection.

THE VERTICAL LANTERN; A NEW INSTRUMENT OF DEMONSTRATION.

By HENRY MORTON, Ph.D.,
President of the Stevens Institute of Technology.

DURING a visit to Cambridge, Mass., last summer, Prof. J. P. Cooke was kind enough to show me an arrangement, which he had been using for several years, for the projection, on a vertical screen, of objects, such as "cohesion figures," which require to be kept in a horizontal position.

To effect this result a square box, containing a diagonal mirror, was attached to the front of a large lantern, so that the rays proceeding from the condensers were thrown vertically upon the object, such as a tank of water, placed above. Over this, again, was supported the object-glass, and a mirror, silvered on its front surface, by which the image was thrown on the screen. Among the objects which were then shown, I was particularly impressed with a tank of water, in which waves being made by falling drops gave a beautiful pattern of interfering lines and curves in delicate grey tints upon the screen.

The only defect in the action of this instrument was the want of an equal illumination in the field, resulting from the separation of the object from the front of the condenser.

I was so favourably impressed with the apparatus, however, that at the earliest opportunity I prepared a design, and had the instrument represented in the accompanying cut constructed by Messrs. Hawkins and Wale, apparatus makers to the Stevens Institute.

Its arrangement was as follows:—The lantern condenser in the first place was made of three lenses, the first two of such curve as to give with the light, at about two inches from the nearer one, a practically parallel beam, which was received upon a mirror, A B, at 45° , and, after reflection from it, fell upon the third lens placed horizontally at C, which concentrated it on the objective at E, from which it passed to the mirror, F G, which, in turn, threw it on the screen. This mirror, moreover, was not silvered on the exterior surface, but in the usual way, though with pure silver, on the back, and yet no want of definition was to be perceived in the image, owing, no doubt, to the fact that the faint reflection from the first surface was inappreciable in comparison with that from the metallic silver. In several articles published in the *CHEMICAL NEWS* and elsewhere, a square prism has been described as being used for the same purpose, but a little thought, or, still better, a moment's experiment, would show that this means would not answer, because about one-third of the cone of rays entering the prism would be at too great an

solution of chloride of tin, are among the illustrations specially suited to this instrument, and I have lately added another, by so supporting a large glass Chladni plate as to bring one of its corners over the condensers, covering this with a thin layer of water, kept in place by a thin ring of rubber cemented to the glass, and exciting the plate with a violin bow. The entire screen is then covered with a beautiful pattern of crispations, varying with the sounds obtained by variously damping the plate. This experiment I used with great satisfaction at a lecture lately delivered in the Academy of Music in Philadelphia, a building which seats over 3000 persons. This will afford some idea of the efficiency of the apparatus; I have, in fact, been greatly surprised by the amount of light which reaches the screen from this apparatus, which is far in excess of what I anticipated when considering the two reflections and other causes of loss.

ON RECENT INVESTIGATIONS AND APPLICATIONS OF EXPLOSIVE AGENTS.*

By F. A. ABEL, F.R.S., Treas. C.S.

In submitting to the Members of the British Association some account of recent progress made in the production and application of explosive agents, I cannot attempt to give much more than an outline of the nature and results of important investigations which have been instituted, and are still being pursued, relating to the development and regulation of the explosive force of gunpowder, and to the application of some other explosive materials, which are already supplanting gunpowder in several of its important uses.

The manufacture of gunpowder required for war purposes was carried on here and abroad for very many years without any important modification. The system pursued in this country in effecting the incorporation of the ingredients, and in converting the mixture into granulated gunpowder, of sufficient density and hardness to enable it to resist injury by transport and storage in all climates, furnished a product which was greatly superior to the generality of foreign gunpowders in regard to its keeping qualities, but which was also more violent in its action, because, in fact, the conditions essential to a rapid and complete transformation of the several constituents were more thoroughly fulfilled in its manufacture; and which hence earned on the Continent the name of *poudre brutale*.

The comparatively small charges used even with the heaviest cast-iron smooth-bore guns, which, until recently, constituted our most powerful armaments by sea and land, were, however, regarded in this country as not unduly trying to the endurance of those guns; and although, about fourteen years ago, some attention was directed to the question of modifying the form or proportions of heavy guns with a view to increase their durability, in consequence mainly of some very instructive experiments instituted in America by Major Rodman, it was not until some little time after the first great stride was made in the increase of power of our artillery (by the introduction of the 110-pounder Armstrong rifled wrought-iron gun), that attention became seriously directed to the importance of attempting to reduce the violence of action, or rapidity of explosion, of the gunpowder to be employed in the increased charges required to impart the requisite velocity and accuracy of flight to comparatively heavy projectiles.

A comparison of the weight of shot and of the charges of powder used in the heavy guns of the present day, with those employed in the most formidable cast-iron siege and naval guns, will at once show how greatly the conditions must have become modified which attend the application of gunpowder to projectile purposes. Much has been

angle for total reflection, and would thus leave one-third of the field dark.

In producing waves in a tank of water, I have used with great satisfaction a little apparatus devised by Messrs. Hawkins and Wale, consisting of a metallic box with a sheet rubber cover, provided with a long thin metal tube; this was so placed that the tube was about one-quarter of an inch above the point in the tank which it was desired to make the centre of the wave motion. On tapping the rubber diaphragm, a momentary puff of air was driven from the tube, producing exactly the disturbance needed. An elliptical ring being placed in the tank, the properties of that curve with regard to reflection are very neatly exhibited, and, in fact, independent of their scientific interest, nothing could be more charming than the pearl-grey waves, crossing and interlocking and combining in complex patterns, which raced across the screen.

"Cohesion figures," "magnetic spectra," and the metallic vegetation developed by an electric current in a

* A Lecture delivered to the Members of the British Association at Edinburgh, August, 1871.

written and said, especially of late, as to our having been far behind other nations in devoting attention to the modification of gunpowder, with a view to meet the altered conditions attending its application in the heavy guns of the present day; but the fact is, that not only were the first investigations into the action of fired gunpowder made in this country, but steps were also taken in England, almost as soon as in any other country, towards the production of a gunpowder, by employment of which the full powers of heavy guns may be developed with the least detriment to their durability.

In 1858 a small committee was appointed to determine upon the best description of gunpowder to be used in the Enfield rifle, and not long afterwards this committee was instructed to extend its inquiry to cannon powder—the most powerful gun of the service at that time being the 110-pounder Armstrong gun. One of the members, General (then Captain) Boxer, had, some few months previously, called attention officially to the desirability of modifying the action of the charges of powder used in the larger natures of guns, either by employing a weaker powder, or a larger grain and denser powder, the charge being increased in amount in order to obtain the same average pressure, and, consequently the same initial velocity, as furnished by the quick powder then used. A careful consideration of the directions in which gunpowder was susceptible of modification, with a view to the reduction of the rapidity of its explosion, led the committee to institute a series of experiments, which resulted, in the first instance, in the introduction into the service, in 1860, of the so-called rifle large-grain powder for all rifled guns, and subsequently in the provisional introduction of pellet-powder for the heavier natures of ordnance. The means and appliances at the command of this committee for carrying out their experimental investigations were small and imperfect: but the results at which they arrived not only served as the starting-points of the successful results attained by the present Committee on Explosive Substances, but also became known to and aroused the attention of Continental Powers, through the agency of officers who visited this country at about the time of the Exhibition of 1862, at which date pellet-powder had already been experimented with for some little time. In America experiments on gunpowder were vigorously pursued at the same time as they were being slowly carried on, with comparatively imperfect means, in England, and the particular form of powder known as prismatic, the production of which was developed in Russia a few years ago, and which has been to some extent adopted in Prussia, appears to have been of American origin, though it has not found favour in that country, where a gunpowder similar in form and size to the new powder known as *pebble* is employed in guns of large calibre, under the name of *mammoth powder*.

The principles laid down by the first Committee on Gunpowder, in 1858, as their guide in attempting to reduce the violence of action of powder when fired in large charges, have been, up to the present time, adhered to by those since entrusted with the continuance of these investigations. Before specifying them it may be instructive to glance briefly at some ways in which gunpowder may readily be modified, with the object of increasing or diminishing the rapidity and violence of its explosion, and at the reasons why they have not hitherto been selected.

As gunpowder is simply an intimate mechanical mixture of a powerful oxidising agent—saltpetre or potassium-nitrate, with two readily-oxidisable substances, sulphur and carbon or charcoal—it is obvious that the behaviour of this mixture, *i.e.*, the rapidity with which it will explode, and the nature of the results furnished by its explosion, are susceptible of great modification by variations in the proportions of its ingredients.

According to the long-accepted chemical theory of the action of gunpowder, the function of the charcoal was to undergo conversion into gas by partial or complete oxidation (*i.e.*, by conversion into carbonic acid or carbonic

oxide), according to the proportion which it bears to the saltpetre employed, while the sulphur was considered to act in two ways—firstly, in promoting the ready ignition of gunpowder by reason of its great inflammability; secondly, by uniting with the potassium in the saltpetre, and thus rendering available the whole of the oxygen for the oxidation of the carbon.

That this view is, to say the least, only a very imperfect explanation of the action of the ingredients in gunpowder, has long since been demonstrated; but the broad facts are undoubted that the rapidity of explosion of a mixture of these three substances may readily be increased or diminished by modifications of the proportions of sulphur or charcoal, or of both, with which the saltpetre is mixed. A very notable difference may be observed in the rate at which two trains will burn, which consist of gunpowders in other respects alike, but differing, for example, in the proportion of charcoal which they contain.

A comparison of the composition of English and foreign gunpowders shows that some of them differ considerably from each other as regards the proportions of their ingredients; and there can be no doubt that these differences may exert a very decided influence upon the action of these gunpowders.

The extent to which the charcoal employed in their preparation has been burned (*i.e.*, the duration of the carbonising process, or the temperature at which it has been effected), and its consequent composition, also vary considerably, and it has been abundantly demonstrated, by the more recent experiments conducted at Woolwich, that, the other characters of cannon powders, tried one against another, being alike, the violence of action increases in direct proportion to the amount of volatile constituents (as indicated by the proportions of hydrogen and oxygen) which have been allowed to remain in the charcoal. This result was observed many years ago in connection with powder for snail arms, the French having found that a highly inflammable charcoal (*charbon roux*), produced by exposure of wood to a comparatively low temperature, furnished a very violent gunpowder, which, on account of its destructive action upon the firearm, was termed *poudre brisante*. It was, however, not known that apparently small differences in the composition, and consequently in the physical properties and ready inflammability of the charcoal might be productive of very considerable differences in the action of gunpowder even when employed in large charges.

It need scarcely be pointed out after what has been said regarding the influence exerted by certain variations of composition upon the rapidity of explosion and consequent violence of gunpowder, that different modifications in the composition of powder, which are opposed in the results they produce, may be made more or less completely to neutralise each others effects. Thus, the reduction in rapidity of action of gunpowder, which may be effected by a diminution in the proportion of the inflammable ingredient sulphur, or of the oxidising ingredient saltpetre, may be counteracted by the employment of a slackly-burned, and therefore highly inflammable, charcoal; and in this way it may be possible that the composition hitherto fixed for gunpowder in this and some other countries may be susceptible of modification, with advantage in point of economy.

Sufficient has been said on this head to show that the explosive action of gunpowder is susceptible of very extensive modification by variation of its composition. But inasmuch as the force exerted by gunpowder is due not simply to the actual amount of gaseous products resulting from the explosion, but also, and in the largest proportion, to the heat developed by the chemical action, it follows that there must be particular proportions of ingredients which, leaving other conditions out of consideration, would appear the best, as furnishing the largest amount of gaseous matter compatible with the development of the highest temperature.

There can be no doubt that the proportions of saltpetre,

sulphur, and carbon, fixed upon in the earlier days of gunpowder manufacture (and which have hitherto undergone no very considerable modification, and indeed none made with any definite design), were not fixed upon by any theoretical considerations, but were purely the result of tentative experiments; but they very nearly correspond to those required for the development of the most energetic action of the saltpetre upon the carbon (regarding the charcoal for a time as pure carbon), though they are not calculated to furnish the largest amount of gas from a given weight of the mixture. The latter result would necessitate the employment of the carbon in the proportion to produce carbon monoxide, or carbonic oxide; while the amount actually used in gunpowder is approximately that required to produce only carbon dioxide or carbonic acid, assuming the sulphur only to exercise the function above indicated, and not to take to itself any of the oxygen of the saltpetre. It has now been long established that the sulphur does at any rate undergo partial oxidation; but it is also admitted that the employment of the proportions of saltpetre, carbon, and sulphur, indicated by the old theory, which provided for the full oxidation, or conversion into carbonic acid, of the greater part of the carbon, furnished a mixture by the explosion of which a comparatively very great amount of chemical energy, and consequently of heat, is developed (or of pressure, when the charge is confined).

It is upon such considerations as these that the late Committee on Gunpowder came to the conclusion that, in attempting to moderate the explosive violence of gunpowder when used in large charges it was inadvisable to make any change in the established composition of gunpowder which might be productive of a diminution of the total pressure developed by a charge, unless the desired results were unattainable by modifying the mechanical and physical characters of powder—in other words, by introducing changes in the *preparation* of gunpowder, and in the *form* in which it is employed. It required but few experiments to demonstrate that the rapidity of explosion of gunpowder was readily susceptible of great reduction by simple mechanical means, and hence those means have been adhered to by the present Committee on Explosive Substances, in elaborating the powder now manufactured for naval and siege guns.

The degree of perfection to which the ingredients of powder are prepared by grinding, and afterwards mixing or incorporating, affords an obvious means of modifying the rapidity of explosion of the mixture, but it would also evidently be both unphilosophical and unpractical to reduce the rapidity of burning of powder by diminishing the degree of completeness to which the ingredients would react upon each other, and thus employing them wastefully, which would be the case if they were not converted into as intimate a mixture as is attainable by known means and appliances. But, starting with as perfect a mixture as can be prepared of the ingredients in the proportions calculated to furnish the maximum attainable change of volume (and consequently of total pressure at the time of explosion), there are five different directions in which gunpowder may be modified as regards its physical and mechanical characters, and the means thereby presented of regulating the rapidity of explosion, have, up to the present time, proved quite sufficient for all requirements. These variable points are—the *size* of individual masses composing the charge of powder; the *form* of these masses, and the *mechanical condition* of their exterior; the *density* or compactness of the masses, and their *hardness*. The size and form of the masses are readily modified by moulding the meal powder into forms of a particular size and shape, as in the case of pellet-powder, prismatic, cubical, or spherical powder; or by breaking up, to a greater or less extent, and in a symmetrical or irregular manner, cakes of compressed powder of different thicknesses, thus producing what is called granulated powder, which ranges in size from fine sporting powder to pebble powder. The surfaces of these masses may be left in their

original rough condition, or they be more or less smoothed and deprived of sharp angles and edges by means of attrition and subsequent glazing or coating with graphite; and their ready inflammability may be correspondingly reduced. The density or compactness of the powder is determined by the pressure to which the material is submitted when converted into slabs, pellets, or other forms; and the hardness is regulated by the proportion of moisture contained in the powder at the time that it is submitted to pressure.

Experience has shown that it requires a very careful adjustment of the several mechanical and physical characters of gunpowder to reduce the rapidity of its action, and at the same time to develop the requisite total pressure and consequent velocity with sufficient uniformity. The first promising result obtained by the late Committee on Gunpowder were simply arrived at by increasing the size of the masses composing the charge; subsequently it was found that the results were greatly improved by paying attention to the density and hardness of the powder, and by adopting measures to promote uniformity in regard to these properties of the powder-particles composing a charge, the importance of which has become more evident as the means available for examining the action of fired gunpowder have been extended and perfected.

A very brief examination only can be attempted of the results which have been arrived at by earlier experiments with regard to the pressure developed by exploding gunpowder, and of those quite recently obtained by the Government Committee on explosive agents.

Although the first attempt was made by a Frenchman, M. de la Hire, in the beginning of last century, to explain the action of fired gunpowder, it was Robins who first investigated the subject experimentally, by carefully determining the quantity of gas generated by the explosion, and by endeavouring to estimate from experimental data the increase of elasticity of the gases due to the temperature developed by the explosion. He came to the conclusion that the permanent gases evolved from powder occupy about 240 times its volume, at normal temperature and pressure, and that the heat generated raised this volume to 1000 times that of the powder, causing the latter therefore to exert a force corresponding to a pressure of about 1000 atmospheres, or $6\frac{1}{2}$ tons on the square inch. The first experiments, of which the object was a direct determination of the pressure exerted by gunpowder when exploded in closed vessels, were made by Count Rumford in 1793, who confined a small charge of sporting powder (not more than 18 grains), in a very strong wrought-iron vessel, the opening of which was closed by means of a weight. The vessel or species of gun was supported vertically, and the charge was exploded by applying a red-hot ball to the lower extremity of the vessel, which formed a closed vent and was filled with powder. A given charge having been employed, the vessel was closed by a weight which was considered likely to be equivalent to the gaseous pressure to be developed. If this weight was raised by the explosion of the particular charge used, it was increased until it just resisted the force exerted by the explosion; this weight was then taken to represent the pressure exerted by the powder. The results obtained by Rumford were conflicting, but the conclusion arrived at by him was, that the total force developed by the explosion of gunpowder corresponded to 101,021 atmospheres, or a pressure of 662 tons upon the square inch. Rumford endeavoured to reconcile the development of this enormous total pressure with the fact that guns could endure it, by assuming that the explosion of powder takes place very gradually in a gun, being completed only when the shot leaves the bore.

Another method, first suggested by Colonel Cavalli in 1843, of determining the pressure in a gun's bore, consisted in inserting a number of small tubes or gun-barrels into the gun along its length; spherical bullets were inserted into these barrels, and the pressure at different parts of

the gun was estimated by ascertaining the velocities by which these balls were propelled when the gun was fired. An improved form of the same method of experiment was adopted in 1854 by the Prussian Ordnance Committee, but was only applied to guns of small calibre. It consisted in fitting a small gun-barrel into a hole drilled into the powder-chamber of the gun; after the gun was loaded, a cylinder, having the same longitudinal section as that of the projectile in the gun, was inserted into the small barrel. Assuming the pressure in the powder-chamber to be uniform throughout, the cylinder and the shot would travel through equal spaces in the same time, and the cylinder, after having travelled eight inches, would be out of the sphere of action of the gas. If the cylinder had a longitudinal section one-half that of the shot, it would require double the velocity, and so on; and thus, by knowing the relation of the longitudinal section of the cylinder to that of the projectile, the velocity of the latter, after it had prescribed a particular distance, could be ascertained by determining that of the cylinder.

The results of the Prussian experiments indicated that the maximum pressure in a 6-pounder gun is 1100 atmospheres, and in a twelve-pounder 1300 atmospheres. The same method subsequently applied to a 70-pounder rifled gun appears to have given an indication of a pressure of about 3000 atmospheres.

(To be continued).

NOTE ON TRINITRO-THYMO-METHOL.

By ROLAND J. ATCHERLEY.

THYMO-METHOL, prepared by acting upon a solution of thymol in methyl iodide with metallic sodium, is dissolved with the aid of a gentle heat in concentrated sulphuric acid, and added very cautiously, by means of a small pipette, to fuming nitric acid. The resulting deeply-coloured solution is diluted with a quantity of water. A large proportion of a resin will then rise to the surface, which may, when cold, be easily removed, while a fused substance remains at the bottom of the vessel. This, when crystallised from alcohol, constitutes trinitro-thymomethol. It forms beautiful iridescent plates of a yellowish colour, fusing at 92° C., and exploding when heated on platinum foil. It is only slightly soluble in boiling water, but easily dissolves in alcohol and ether. Sulphuric acid dissolves it likewise; it is, however, re-precipitated on dilution with water in an unaltered state. Analysis shows it to be represented by the formula $C_{11}H_{13}O(NO_2)_3$. I have not yet succeeded in converting it into an amide, but hope shortly to do so, as well as to prepare the mono- and di-nitro derivatives of thymo-methol.

NOTICES OF BOOKS.

The Technical History of Commerce; or, Skilled Labour applied to Production. By JOHN YEATS, LL.D., F.G.S., F.R.G.S., &c., assisted by several Scientific Gentlemen. London: Cassell, Petter, and Galpin.

DR. YEATS considers all branches of industry as grouped under three heads, viz., Materials, Labour, and Commerce; and to each he devotes a volume of his series, of which the present is the second published, the former being entitled "The Natural History of the Raw Materials of Commerce." Industry is divided into:—Mechanical, comprising Engineering, Manufacturing, Mining, &c. Chemical—Bleaching, Dyeing, Smelting, &c. Physiological—Dealing with Agriculture, Gardening, and Cattle-rearing. And Mental, with Education and Government. After considering the origin of the useful arts and the knowledge possessed of them by the ancients, their present application is outlined, and it is from the clear definition of this outline that the full worth of

the work obtains. Dr. Yeats thinks with Sir Humphry Davy, that all the great changes of nations are not to be confounded with changes in their dynasties, but that these changes are dependent upon the opinion of the people, and the peculiar spirit of the age and nation. The illustrative facts are drawn from all sources, and greatly from Germany, where the author, it appears, spent some time in studying the application of chemical and mining science. It must be borne in mind that Dr. Yeats is the head-master of a large school, and that this work is written for the use of his boys, not only while they are with him, but to serve the purpose of an introduction to the literature of the particular branch of industry the student may eventually follow, not forgetting that there are many established commercial men to whom Dr. Yeats's work will convey much that is interesting. The work enlarges the scope of our school books, showing how they may be written to be preserved in after life, not for mere curiosity, but for actual information. These volumes should certainly accompany the usual text-books of "our sixth."

CORRESPONDENCE.

SPECTRUM OF LIGHTNING.

To the Editor of the Chemical News.

SIR,—We had here, during a thunderstorm on Monday night, a magnificent display of lightning, the spectra of which I examined, but having only a pocket spectroscope, I was unable to determine the position of the bright bands with any degree of accuracy.

Two narrow blue-green bands most frequently made their appearance; they were somewhat narrower than those of the chloride of copper spectrum, and separated by a wider interval. At times when the flashes were particularly vivid, bands of various degrees of luminous intensity and of breadth were distributed over the whole spectrum; and, during the occurrence of a flash *en zigzag*, a group of narrow ones—two being very brilliant—appeared in the more refrangible part of the red, besides those bands in the blue and green, which were always most conspicuous.

The complexity of these spectra gave me the impression that this department of meteorological chemistry would prove a most promising field of investigation.—I am, &c.,

JOSEPH GIBBONS.

Tywardreath, Cornwall,
August 16, 1871.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 31, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Second Memoir on the Action of Electricity upon the Coloured Tissues of Plants.—M. Bequerel.

Glacial Origin of the Peat Deposits of the Neuschâtel Jura, and on the Plants met with therein.—Ch. Martius.—A geologico-botanical essay.

New Mineral Found in the Tin Ore Deposit of Montebraz (Creuse).—M. Moissenet and M. Des Cloizeaux.—This paper contains a brief description of the results of the mining operations at Montebraz, where tin ore is found, and, among other minerals, also a fluo-phosphate of alumina, soda, and lithia, which will be mineralogically known as montebrasite. The composition of this substance, in 100 parts, is quoted as follows:—Fluorine, 26.50; phosphoric acid, 21.80; alumina, 38.20; soda, 6.70; lithia, 6.50; lime, 2.0; quartz (intermixed, not really belonging to the mineral), 2.25; loss by ignition, 0.60. Qualitatively, this mineral contains the same constituents as the ambygonite from Arnsdorf, but in the montebrasite a three times larger quantity of fluorine occurs; the sp. gr. of the last-named mineral is 3.11. The formulae given are $2(\text{Al}_2\text{F}_{13}\text{M}_3\text{F}_3\text{P}) + 4\text{Al}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5$, and the atomic formula, $\text{Al}_4\text{M}_4\text{O}_{10}\text{F}_{14}\text{P}_4$. Wavellite and turquoise are also met with in the tin ore deposit alluded to.

Reversion of the Spectrum-Rays of Metallic Vapours.—A. Cornu.—A lengthy spectroscopical memoir.

New Method of Incineration of Vegetable and Animal Substances, and the application of that method to the Estimation of the Mineral Elements of Yeast.—A. Béchamp.—After first referring at length to the difficulty often experienced by analytical chemists, to ignite and burn off completely certain organic substances, especially such as yield a readily fusible ash, the author proposes the use of nitrate of bismuth in the state of an aqueous solution of known strength to be mixed with the material to be incinerated (in this paper yeast is only mentioned, and it is a well-known fact that that substance is very difficult to burn off completely), provided the water contained in the substance has been previously ascertained by drying at 100°. The nitrate of bismuth solution (the bulk thereof to ignite and calcine readily 100 to 150 grms. of substance should contain from 3 to 4 grms. of oxide of bismuth) having been mixed with a fresh and weighed portion of the yeast, the mixture is first dried gently on a water-bath, next heated on a sand-bath hot enough to cause the mass to blacken, after which it burns away as tinder, and, if required, the ignition is completed over the lamp. Should any fear exist that some metallic bismuth should have been formed, nitric acid is added to the ash, and the heating repeated, so as to destroy the nitrate of bismuth thus formed. The author, not desiring to estimate the chlorine in the ash of the yeast he had operated upon, dissolved that ash in hydrochloric acid, and removed the bismuth by means of sulphuretted hydrogen. This paper contains also a series of results of ash analysis of yeast made by the method alluded to.

Discovery of a Bone Cavern near Montjeu (South of France).—M. Piette.

Bone Caverns of Baoussé-Roussé (Italy).—E. Rivière.—This and the preceding paper are contributions to geology and palæontology.

Zeitschrift für Chemie von Beilstein, No. 8, 1871.

The original memoirs and papers contained in this number are—

Conversion of Dichlorhydrine boiling at 174° into that boiling at 182°.—H. Hübnér and C. Müller.—By treating an allyl-alcohol (prepared from a dichlorhydrine boiling at 174°) with dry chlorine gas, the authors obtained a dichloride different from that which they expected to obtain (one that should boil at 174°), but a dichlorhydrine boiling at 182°, identical with that which is obtained by the action of chlorine upon allyl-alcohol from glycerine and oxalic acid.

On a Brom-Sulphotoluol and a Sulphotoluol.—H. Hübnér and N. M. Terry.—The authors first describe the preparation of solid brom-toluol, a crystalline substance, fusing at 28°, and boiling at 185°; sp. gr. at 30°, 1.3999. This substance was first dissolved in fuming sulphuric acid, and several a sulphotoluol salts prepared. The a sulphotoluol, $\text{C}_6\text{H}_4\text{CH}_2\text{SO}_3\text{OH}$, is a crystalline substance, soluble in water. The lead-salt of this acid, $[\text{C}_6\text{H}_4\text{CH}_2(\text{SO}_3\text{O})]_2\text{Pb} + 4\text{H}_2\text{O}$, is a crystalline compound readily soluble in water. Nothing is mentioned in this paper on a brom-sulphotoluol.

The Sulpho-Acids of Benzol.—Dr. H. Rose.—The author describes the preparation of a sulpho-acid of benzol by treating pure nitrobenzol with fuming sulphuric acid, and next forming, first a baryta salt, from which the free sulpho-benzol acid was separated. That free acid is a solid substance, soluble in water and alcohol, hygroscopic, fusing between 60° and 70°, and insoluble in ether. The baryta salt, $\text{C}_6\text{H}_4\text{NO}_2\text{SO}_3 \cdot 2\text{Ba} + \text{H}_2\text{O}$, is crystalline, yellowish coloured, somewhat soluble in water, and insoluble in alcohol. The paper further contains the catalogical quotation of several other salts of this acid.

Product of Decomposition of the Chloromethyl-Sulphurous Acid.—N. Jazukowitsch.—While preparing trichloromethyl-sulphite of potassa by treating the chloride of the acid alluded to with excess of caustic potassa solution, the author observed the formation of a salt insoluble in water, which was found to be also insoluble in alcohol, and to consist of $\text{CH}_2\text{SO}_3 \cdot \text{K}_2\text{O}$. This salt is the potassa salt of a bibasic acid, which, however, could not be obtained in free state.

Ethyl-Diacetic Acid and some of its Derivatives.—A. Geuther.—This monograph contains the following sections:—Best method of preparation of ethyl-diacetic acid; action of pentachloride of phosphorus upon ethyl-diacetic acid; monochlor-quartenylic acid; monochlor-tetraeylic acid, $\text{C}_4\text{H}_7\text{ClO}_4$; sodium salt—

oil product; quartenylic acid, $\text{C}_4\text{H}_7\text{O}_4$; tetraeylic acid (solid crotonic acid); tetrolic acid; on diethyl-diacetic-amide, and the action of ammonia upon heated ethyl-diacetic acid ether.

Researches on the Allyl Group.—B. Tollens, A. Rinne, and G. Munder.—This essay is divided into the following chapters:—Con-

version of allylic alcohol into normal propylic alcohol; oxidation of allylic alcohol; on allyl-cyanide (croto-nitrile); conversion of the chloride of allylic alcohol into the dichlorhydrine isomeric therewith.

Estimation of Chlorine, Bromine, and Iodine according to Carius's Method.—B. Tollens.—The author states mainly that small glass globules containing bromated or other substances, when heated in sealed tubes, along with nitric acid of 1.2 sp. gr., up to 160° and 220°, when made of ordinary glass, lose from 0.0007 to 0.0029 grms. in weight; while globules made of Bohemian glass (best combustion-tube glass) lost, after six hours' heating to 220° along with nitric acid, only from 0.0008 to 0.0012 grms. By the application, therefore, of Carius's method, the glass globules should be made of best Bohemian glass, since ordinary glass, even if free from lead, is strongly acted upon by nitric acid under the conditions alluded to.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 6, 1871.

The original papers and memoirs contained in this number relate to geology, palæontology, mineralogy, and geometry.

Les Mondes, July 27, 1871.

This number opens with an article entitled—

Salle du Progrès.—Rev. F. Moigno.—The excellent and enlightened editor of the above-named periodical states, in this short paper, that he intends shortly to open, with the assistance and collaboration of others, a campaign against what the writer terms "l'ignorance, une des grandes plaies de la belle France," in other words, to begin, in various districts of Paris and localities of France, a series of lectures suited to the general public, and intended to render true, in a moral, material, as well as scientific sense, the "ingenus didicisse fideliter artes emollit mores nec sinit esse ferus."

This number further contains the following matter relating to chemistry and collateral sciences:—

Light and Electricity.—P. Breton.—This paper, illustrated by a woodcut, does not contain a description of any experiment already made, but suggestions on researches which might, if made with care, perhaps tend to illustrate something concerning the nature of the undulations of the ether which produce the phenomena of light and electricity.

Essay on the Comparative Geology of the Vosges, Pyrenees, and Central Mountain Plateau of France.—Dr. G. Bleicher.—An important contribution to geology, here briefly reviewed, the original work having been published last year at Colmar.

Best means of bringing Waste Lands into Cultivation.—Rev. F. Moigno.—Although the contents of this paper bear more especially upon France, there is much in it suitable for application to other countries where heath, marsh, and moor land are yet found waiting to be turned to useful account.

New Manometer for Measuring High Pressure of Gases.—V. Regnault.—Illustrated by engravings; while, moreover, the contents of this paper are strictly algebraico-physical.

Aurora Borealis seen and observed in Italy on the 6th, 18th, and 23rd of April last.—Rev. Father Denza, S.J.—To this lengthy paper is added a short appendix, stating that, on the nights of the 7th, 12th, and 18th of June last the phenomenon alluded to was brilliantly seen in various parts of Italy, and accompanied by strong magnetic perturbations.

August 3, 1871.

Central Scientific Office for the Netherlands.—Dr. E. H. von Baumhauer states that, in imitation of what obtains in the United States, where the Smithsonian Institute at Washington is the central office for exchange of publications and periodicals of the learned and scientific societies, it has been arranged that, for the Netherlands, this will be the Hollandache Maatschappij voor Wetenschappen (Holland Society of Sciences), at Haarlem, to which the *savant* just named is the Secretary. A large number of the various scientific and learned societies in different parts of the Netherlands have intimated their intention of sending and obtaining their exchanges by the mode mentioned. M. J. Baillière and Son, at Paris, are provisionally nominated as the agents of the office at Paris for France.

August 10, 1871.

Origin of the Principal Currents of Air (Wind).—Dr. Lar-tigue.—A meteorological essay.

Cause of Explosion (Accidental and Spontaneous) of Explosive Substances, and on a Preventative of such occurrences.—Dr. Zaliwski.—The author says that the explosive property of the inflammable substance depends upon the hygrometric condition of the atmosphere—that is to say, that gunpowder and other explosive materials become, even without elevation of temperature, spontaneously explosive, and that the smallest trace of oxalic acid is, if mixed with the explosives, sufficient to prevent spontaneous explosion due to the cause alluded to, owing to a catalytic effect which precedes the loss of basic water of the acid alluded to. The author further says that this fact can be readily experimentally proved by adding, to a mixture of sulphur and chlorate of potassa, for instance, or to any other explosive mixture, a certain quantity of oxalic acid, after which these materials may be heated even up to their point of fusion without exploding.

Bayerisches Industrie und Gewerbe Blatt, May, 1871.

This number contains the following original matter relating to chemistry and collateral sciences:—

Schweizer's Coating for Stereochromic and other Purposes.—Dr. Fechtinger.—This lengthy paper contains a detailed account of the results of the practical application of what, in reality, is a peculiar cement or stucco mass, consisting of pulverised chalk, or marble, quartzose sand, cement, and silicate of potassa solution, which, originally employed, and first applied, by M. Schweizer, at Munich, has been used in that city for various architectural and other purposes, among others, the coating of sheets of iron, zinc, &c., upon which coating stereochromy was applied.

Chinese Varnish.—Dr. v. Scherzer.—Under the name of schio-liao, the Chinese apply as varnish freshly-defibrinated blood, mixed with powdered slaked lime, and a small quantity of alum, in the proportion of 3 parts of previously-defibrinated fresh blood, 4 parts of lime, and a small quantity of powdered alum. The result is the formation of a glutinous yet fluid mass, which is ready for use at once, and especially used for rendering wood perfectly water-tight, and harden its surface. The author states that he has seen in China bags made of straw rendered so impervious for liquids by the application of this varnish as to serve for the transport of oil, while thin millboard painted with this varnish becomes as hard as wood.

Preventatives for the Ignition of Woven Fabrics.—A. Patera.—The author recommends the use of a solution consisting of—Water, 20 parts; borax, 3, and sulphate of magnesia, 2½ parts. These salts are only to be mixed just previous to use. The muslins and other similar fabrics are thoroughly impregnated with the solution, next wrung out, and are, after having become nearly dry, ironed. The use of a mixture of sulphate of ammonia and sulphate of lime is also recommended. And, lastly, attention is called again to the application first made by Fuchs, so far back as 1823, of a solution of silicate of potassa, or soda, for rendering wood, and especially theatrical decorations, fire-proof, that is to say, preventing such from bursting into flame if accidentally ignited.

Action of Moist Ultramarine upon Silver.—J. N. Braunschweizer.—The author relates at length a series of experiments made by him, in order to explain some facts to which his attention had been called by parties, who found that silver foil (perfectly pure silver) and objects made of that metal—spoons and forks—became very deeply black-brown coloured under conditions which seemed to point to the presence of ultramarine (in paper wherein either the objects were packed, or in contact with) as the only cause of the discolouration and tarnishing of the metal alluded to. By the experiments, this opinion was fully confirmed, care being taken to have extra good quality of ultramarine, and to institute comparative experiments with other blue pigments, viz., indigo, litmus, Berlin-blue, mountain-blue, all of which, placed upon clean glass plates, and moistened with distilled water, were left in contact with silver foil for twenty-four hours, with the result that only the foil in contact with ultramarine was blackened. It thus appears that the sulphuret of aluminium present in ultramarine is slowly decomposed, and gives off, when moist, sulphuretted hydrogen.

Improved Mixtures for Red, Green, and Blue Bengal Lights.—J. N. Braunschweizer.—The following mixtures have been found, after a series of experiments, to be the best:—For red, 9 parts of nitrate of strontia, 3 parts of shellac, 1½ parts of chlorate of potassa; for green, 9 parts of nitrate of baryta, 3 parts of shellac, 1½ parts of chlorate of potassa; for blue, 8 parts of ammoniacal sulphate of copper, 6 parts of chlorate of potassa, 1 part of shellac. This latter ingredient need only be coarsely pulverised. The mixtures here alluded to are suitable for use in theatres and rooms, as by the combustion no injurious vapours are given off.

La Revue des Scientifique de la France et de l'Etranger, July 29, 1871.

This number does not contain any original papers bearing upon chemistry and allied sciences.

Journal für Gasbeleuchtung und Wasserversorgung, No. 13, 1871.

This number only contains such original matter as directly bears upon gas- and water-works' engineering and management.

NOTES AND QUERIES.

Logwood Test for Alum in Bread.—Can any of your correspondents inform me how the test for alum in bread, known as the logwood test, is performed, or where I shall find a description of it?—F. B. MUNN.

Diamond Dust.—Could your readers tell me, through the medium of your paper, if there is a way of separating glass from jeweller's "diamond dust," the glass having been put in for adulteration?—JOSIAH LOWE.

Manufacture of Alum.—Desiring to obtain the fullest and latest information on alum manufacture, I should be obliged to your readers for directions. Muepratt, Richardson, and Knapp I have.—A.

Carbolic Acid.—(Reply to "Carbolic.")—When quite pure—that is to say, free from other constituents of tar—carbolic acid has no disagreeable smell, and may be used by being dissolved in strong acetic acid, and next diluted with water. In the liquid thus obtained, the smell of acetic acid prevails, so as to make the peculiar odour of the carbolic acid quite imperceptible.

TO CORRESPONDENTS.

. The Students' Number of the *CHEMICAL NEWS* will be published on Friday, September 8th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our Office for publication in that number, will confer a favour by sending it with the least possible delay.

G. Maurice, Paris.—Your communication shall receive attention.
J. G.—The price of Dr. Schellen's work on *Spectrum Analysis*, reviewed in vol. xxii., p. 284, is 12s. 6d.

Dr. F. Grace Calvert, F.R.S., T. Bloxam, M. M. Pattison Muir, Dr. T. L. Phipson, R. J. Atcherley, Dr. C. R. A. Wright, Dr. Thorpe, N. S. Maskelyne, Dr. J. Emerson Reynolds, and J. Alfred Wanklyn.—These correspondents are thanked for their communications.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXIV. No. 614.

LOCALITIES OF DIOPTASE.*

By Professor N. STORY MASKELYNE, F.R.S.

DIOPTASE has hitherto only been known as a product of the copper mine at Altyn Tubeh, in the Kirghese steppes of Tartary, if we except certain reputed localities in Germany; it has been recently met with among old specimens that have been traced to localities in Chili.

One of these was among the specimens preserved in drawers at the British Museum, which have lately been under careful examination with a view to their identification, and another similar specimen was obtained some years since by W. G. Lettsom, Esq., the well-known distinguished mineralogist, from a dealer at Vienna.

The crystals on both are minute but distinct, and are those of diophtase. The gangue is a compact micaceous hæmatite; the locality, traced to an old sale catalogue of Heuland's, is the Rosario Mine, Chili.

It is singular that other specimens of the same mineral should have been found among the carefully preserved treasures of the British Museum. One of these is associated with chrysocolia and ochre on a quartzose veinstone, another occurs as a thin crust on a schorlaceous rock, both being from a Chilian locality. A specimen recently obtained is associated with quartz and eisenkiesel, and is from the Mina del Limbo, Del Salado, Copiapo, Chili.

ON ANDREWSITE.*

By Professor N. STORY MASKELYNE, F.R.S.

A SOMEWHAT well-marked group of minerals would seem to justify the designation of the Dufrenite group, by reason of their having, as a common constituent (or being capable of being so represented), a compound of which the formula is $R_2P_2O_8 + R_2H_6O_6$; R being Fe in the case of Dufrenite.

Dufrenite being $Fe_2P_2O_8 + R_2H_6O_6$, or, in Berzelian symbols, FeP, RH_3 ,

Peganite is $AlP, AlH_3 + 3H$,

Fischerite is $AlP, AlH_3 + 5H$.

Cacoxene is $FeP, Fe_2H_3 + 9H$.

Wavellite is $2AlP, Al_2H_3 + 9H$.

A mineral recently found in Cornwall, and sent to the British Museum by Mr. Talling, may perhaps be referred to this group. It has been analysed in the Museum Laboratory, and Professor Maskelyne named it Andrewsité, in honour of the distinguished President of the Chemical Section of the British Association, Dr. Andrews, of Belfast.

Andrewsité occurs in occasional association with a bright green mineral in brilliant minute crystals, presenting a strongly marked resemblance to those of Dufrenite. This green mineral not having been as yet, from the small amount obtained of it, submitted to analysis, is only provisionally termed Dufrenite.

The Andrewsité which it sometimes thus accompanies presents itself in globular forms or in discs with a radiate structure, and in habit curiously resembles wavellite. Its colour is a slightly bluish green; its surface is generally

formed of a very thin layer of the mineral provisionally termed Dufrenite, crystals of which occasionally stand out of the globules.

The interior of the globules is sometimes homogeneous, and consists of radiating crystalline fibres; oftener one perceives an almost sudden transition from an outer shell of some thickness, which consists of Andrewsité, into an inner core, formed of a brown mineral.

Seen under the microscope, the two minerals appear to a certain degree to interpenetrate each other, so that the selection of material for analysis is a work of much caution.

The spherules usually stand on the projections of a quartzose veinstone, protruding into a hollow, and covered with a mass of limonite, sometimes carrying a drusy crust of Göthite, and studded occasionally with a few brilliant little crystals of cuprite. The spherules are met with in one or two cases on cuprite formed round a nucleus of native copper. Andrewsité, in fact, contains copper, four analyses of separate specimens giving the percentages of—10.651, 10.702, 10.917, and 11.002.

The analyses of Andrewsité have proved sufficiently concordant to justify the formula—

in which, however, a portion of the ferric phosphate is replaced by ferrous phosphate, as in Vivianite is frequently the case with the two phosphates.

The parallelism of Chenevixite ($Cu_3As_2O_8 + Fe_2H_6O_6$) with a portion of the above formula is worthy of attention, and may justify the formula being written as—

A larger supply of the mineral will no doubt soon be forthcoming, when the formula may be fixed on the foundation of more certain analyses. The specific gravity of this mineral is 3.475, that of Dufrenite being (from Siegen) 3.2 to 3.4.

The chalkosiderite of Ullmann, the name by which nearly sixty years ago he designated a thin crystalline coating overlying the radiated variety of the Grüneisenstein (Dufrenite) of the Hollerter Zug, Sayn, Westphalia, does not seem to have been analysed by him. He states it to contain copper, but the subsequent analyses of Grüneisenstein do not appear to confirm this statement; indeed it appears more nearly to resemble the green crystallised mineral which has in this note been provisionally described as Dufrenite.

ON THE GOLD ORE OF NOVA SCOTIA.*

By Dr. T. L. PHIPSON, F.C.S.

THE gold-bearing rocks of Nova Scotia extend along the Atlantic border of the province for a distance of more than 300 miles. They are 12,000 feet in thickness, and are worked, in one district or another, through a vertical space of 6000 feet.

These rocks consist of clay slate and quartz, interstratified, and are supposed to be of lower Silurian age—in some places lying directly upon the gneiss, at others on the Cambrian rocks which cover the gneiss.

The other minerals besides gold found in this formation in Nova Scotia are sesquioxide of manganese, iron pyrites, mispickel (abundant), zinc blende, galena, copper pyrites (sometimes), calcspar, native copper, cuprite, mica, sulphide of molybdenum, malachite, and oxide of iron. But at least one-third of the country is yet unexplored, though it has been 120 years under uninterrupted British rule. In no place has the mining exceeded 300 feet from surface, and it is asserted to be well known that the quartz

* Read before the British Association, Edinburgh Meeting, Section B.

* Read before the British Association, Edinburgh Meeting, Section C.

increases in richness with the depth. The few mines worked from 1860 to 1867 produced together about 3 tons weight (English) of gold, and since then the yield has gone on steadily increasing. I have lately examined a certain number of fine specimens of the above-mentioned rocks from the Pioneer Mine, in the Cariboo district, which has been recently opened. Two of these specimens weighed respectively 12½ lbs. and 8½ lbs. avoirdupois. They consist of a mixture of white quartz and dark green schist (termed clay-slate in the country). A fair sample of these two stones was taken, and 75 grms. of it treated with nitro-hydrochloric acid; the gold being precipitated as usual by sulphate of iron weighed 9 centigrammes. Another analysis gave, on 100 parts—

Gold	0.60
Silver	0.04

The gold stamped out of some rich specimens gave—

Gold	93.75
Silver	6.25

100.00

which is similar to the richer kind of Californian gold.

The average yield of the mines now regularly working by the amalgamation process is about 1 ounce (troy) per ton; but much gold is wasted as well as mercury, as the ore is often very sulphurous, and roasting has hitherto failed from being incompletely carried out without kilns. In some instances the yield has been five to ten times as large, and in many districts, probably 3 or 4 ounces of gold per ton of ore could be reckoned on for a lengthened period. I am of opinion that a moderate amount of English capital and enterprise would soon make this colony one of the most successful gold regions on the globe.

I have examined the green schistous rock which accompanies the white quartz in the Cariboo district above-named, and which, like the quartz, contains gold. I have detected a notable amount of glucina in it and traces of some of the rarer earths. It is a dark leek-green schist, with an unctuous feel, like talc, gives a nearly white powder, which loses 2.32 per cent of water at a red heat, and takes a reddish tinge. It is only fusible with difficulty upon the thinnest edges before the blowpipe, and then whitens. The results of the only analysis I have made of it are as follows:—

Water	2.32
Silicic acid	41.20
Alumina	22.00
Glucina	0.33
Yttria and earths insoluble in potash	{ minute quantity
Oxide of manganese	2.20
Protoxide of iron	15.47
Magnesia	1.44
Lime	1.79
Alkalies	7.65
Portion not attacked by KOCO ₂ + + NaOCO ₂ , with a little gold and silver.	5.60
	100.00

Whether this schistous rock should be termed *clay-slate*, *talc-schist*, *mica-slate*, *nacrite*, or *talcite*, is a question I must leave to the geologist, the composition of all these rocks presenting much similarity. There is a small quantity of peroxide of iron calculated here as protoxide. Gold is present in most of the minerals that are found in the quartz and green schist, especially in the arsenical pyrites and the iron pyrites, some specimens of which are very rich. I have little doubt that vanadic acid, titanitic acid, and perhaps zirconia, could be detected in all these schistous rocks, as well as the rarer earths mentioned above, but I had only a limited period to devote to their examination.

ANALYSIS OF ENTIRE WHEATEN FLOUR.

By A. H. CHURCH, M.A.,

Professor of Chemistry, Royal Agricultural College, Cirencester.

It is well known that fine flour contains less nitrogen than the whole wheat grain. If we endeavour to supplement this deficiency of nitrogenous compounds by the addition of bran, though the chemical conditions of a satisfactory food rich in flesh-formers may be fulfilled, the mechanical texture of the material leaves much to be desired. Anxious to ascertain whether any article of commerce really contained all the materials of the wheat grain in desirable proportions, I made some trials of certain gluten preparations and of Chapman's Entire Wheat Flour. The former scarcely fulfilled the necessary conditions, so far, at least, as fat and mineral matters were concerned, but the latter gave very encouraging results. Two determinations of nitrogen in the entire wheaten flour gave respectively

2.11 per cent nitrogen
2.12 " " "

The mean of these results, when multiplied by the proper factor, 6.33, gives us 13.39 per cent of albumenoids or flesh-formers as contained in this preparation. This is a very large amount, seldom reached, except in certain horny long-grained foreign wheats, or in the translucent grains* of some of our home grown corn. Nor did the ash determination in this flour yield unfavourable indications. While the whole grain of wheat yields generally about 1.6 per cent of ash, the sample of flour now under notice gave 1.04 per cent, which compares well with the low percentage of 0.6 found in ordinary fine flour. This ash was also unusually rich in the most important ingredient of the mineral matter of the wheat grain, containing, as it did, no less than 51.8 per cent of anhydrous phosphoric acid, while the ash of ordinary whole wheat gives, on an average, no more than 46.2 per cent of this ingredient.

DETERMINATION OF NICKEL AND COPPER BY THE BATTERY.

By J. M. MERRICK, S.B.

THE following analyses were undertaken recently to satisfy myself in regard to the accuracy of the electro-magnetic method of determining several metals. They show, in regard to nickel at least, what has already been demonstrated in the case of copper (*vide* Wolcott Gibbs, *Am. Journ. Sci.*, xxxix., pp. 64–65), that, where this method can be used, it is far more accurate, elegant, and satisfactory than any other.

The process employed is very simple. A platinum crucible, holding the solution to be decomposed, was made the cathode of a two- or three-cell Grove's battery, by setting it in the coiled-up end of the wire from the zinc plate, and the circuit completed by dipping into the solution, through a perforated porcelain cover, a platinum wire from the other pole. Some presumably-pure double sulphate of nickel and ammonia was first analysed. One gramme of this salt was found to require about 2½ hours for its reduction, with the aid of a battery of two ordinary Grove's cells.

- 0.9495 grm. of double sulphate gave 0.1405 grm. of metallic nickel = 14.79 per cent.
- 0.4444 grm. of double sulphate gave 0.0657 grm. of metallic nickel = 14.78 per cent.
- 0.134 grm. of double sulphate gave 0.0198 grm. of metallic nickel = 14.77 per cent.

The double sulphate of nickel and ammonia contains, theoretically, 14.72 per cent of nickel (*vide* Gmelin, "Handbook," vol. v., p. 381).

Theory.	a.	b.	c.
14.72	14.79	14.78	14.77

* *Vide* "How Crops Grow," Church and Dyer's edition, pp. 385, 392.

The above analysed salt, which had been supposed to be perfectly pure, had lain for some time in the sun, which may have caused a minute loss of water and so an increased amount—0.07, 0.06, 0.05 per cent; or, possibly, the deposited nickel may have faintly oxidised in drying the crucible.

The next salt experimented with was a commercial sulphate of nickel in coarse powder, roughly dried between folds of filter-paper.

- (d). 0.85 grm. of sulphate of nickel gave 0.1878 grm. of metallic nickel = 22.07 per cent.
(e). 0.3282 grm. of sulphate of nickel gave 0.0718 grm. metallic nickel = 21.87 per cent.
(f). 0.4367 grm. of sulphate of nickel gave 0.0954 grm. metallic nickel = 21.84 per cent.
(g). 0.42 grm. of sulphate of nickel gave 0.09 grm. of metallic nickel = 21.43 per cent.
(h). 0.458 grm. of sulphate of nickel gave 0.101 grm. of metallic nickel = 22.05 per cent.

Sulphate of nickel, of the formula $\text{NiO} \cdot \text{SO}_3 \cdot 7\text{H}_2\text{O}$, should contain 20.71 per cent of nickel.

Theory.	d.	e.	f.	g.	h.
20.71	22.07	22.87	21.84	21.43	22.05

This sulphate of nickel contained crystals of different sizes and of unlike appearance, and no attempt was made to purify it, yet the results obtained, though too high, and showing that the salt was unduly dry, do not differ very widely. The extreme difference is 0.64 per cent, and the least 0.02 per cent.

The double sulphate of nickel and potassium, presumably perfectly pure and twice re-crystallised, was next analysed by the aid of the battery. As this salt does not deposit metal, but only oxide, when no ammonia is present, a considerable excess of ammonia was added to the solution in the crucible.

- (i). 0.5175 grm. of double sulphate of nickel and potassium gave 0.069 grm. of metallic nickel = 13.33 per cent.
(j). 0.305 grm. of double sulphate of nickel and potassium gave 0.0408 grm. of metallic nickel = 13.37 per cent.
(k). 0.5 grm. of double sulphate of nickel and potassium gave 0.0662 grm. metallic nickel = 13.24 per cent.

Theory.	i.	j.	k.
13.29	13.33	13.37	13.24

The extremes here are +0.09 and -0.05 per cent.

A separation of copper and nickel was next attempted. The nickel and copper salts having been dissolved in hot water, the solution was made very strongly acid, and the copper first deposited out from the acid solution. The solution was then made strongly alkaline with ammonia, and the nickel plated out on the same crucible over the copper deposit. Sulphate of copper and the double sulphate of nickel and ammonia were employed. The results obtained, as well as some results with salts of zinc, must be reserved for another paper.

Laboratory, 59, Broad Street,
Boston, U.S., Aug. 1, 1871.

Prussia, and other countries. To ascertain the pressure exerted in any portion of the gun's bore, Major Rodman drilled a hole in the gun at that part, and inserted a hollow cylinder carrying the indicating apparatus. This consisted of an indenting tool, resting upon a piston which fitted into the part of the cylinder nearest to the gun's bore. A small metal cup was inserted at the back of the piston, to guard against any rush of gas past the latter. A flat piece of soft copper was screwed down firmly against the knife-edge of the indenting tool, so that, when the piston was acted upon by the pressure which the exploding powder exerted, the knife was forced into the copper, producing a cut, the dimensions of which were accurately measured, and compared with indentations produced by application of known pressures.

Major Rodman applied this instrument to guns of various calibres up to 11 inches, and instituted several series of experiments, employing in the first instance different natures of cartridges, and afterwards powders of different size of grain, ranging from one to four inches in diameter. The results arrived at presented several anomalies and serious contradictions, but those obtained with the powders of different sizes were, generally, of a nature to warrant a conclusion similar to that arrived at by the late Committee on Gunpowder in the earlier stage of their experiments, namely, that the velocities furnished by small-grain gunpowder may be obtained, with a reduced strain upon the arm, by adapting the size of powder to the calibre of the gun. Major Rodman also fitted this pressure-gauge to a very strong vessel, in which he exploded charges of powder ranging from 700 to 7000 grains, allowing the products to escape through a vent 0.1" in diameter. The pressure-indications obtained by him varied very greatly; in some they corresponded to 4900 atmospheres (or 32 tons to the square inch), while in the others they ranged as high as 12,400 atmospheres (or 82 tons).

In 1869, the present Committee on Explosive Substances were entrusted by Government with the investigation of the action of gunpowder, which had been taken up by the late Ordnance Select Committee in continuation of the Gunpowder Committee's experiments—the special object of the researches being to ascertain the pressures exercised in guns of different calibres by different descriptions of powder, and to deduce from the results the conditions to be fulfilled by a powder susceptible of safe and efficient employment in very large charges. In their earlier experiments the committee employed Rodman's pressure-gauge as one method of registering the pressure developed; but the very variable and anomalous results which that instrument furnished led them to devise a modification of it, in which the principal sources of error attending the use of the Rodman gauge appear to have been successfully avoided, and which, under the name of the crusher gauge, has been since employed throughout the Committee's experiments, in conjunction with another instrument, which will be directly referred to.

The crusher gauge consists of a hollow steel screw-plug, which, like the Rodman gauge, is inserted into holes drilled into the gun at the powder chamber, and at various other parts of the bore. The extremity of the plug nearest the charge is closed by a piston which presses against one end of a soft copper cylinder held by springs in the centre of a small chamber in the plug. The other end of the copper cylinder rests against an anvil. When the gun is fired the piston is pressed against the copper cylinder, and the latter is consequently compressed, thus registering the maximum of force exerted at that particular part of the gun.

The other instrument employed by the committee is a chronoscope, devised and elaborated by Captain A. Noble, by means of which they have been enabled to determine with ease and precision the time occupied by the projectile in traversing different parts of the bore of a gun. The principle of this instrument consists in registering, by means of electric discharges, upon a recording surface, which travels at a very high and uniform speed, the precise

ON RECENT INVESTIGATIONS AND APPLICATIONS OF EXPLOSIVE AGENTS.*

By F. A. ABEL, F.R.S., Treas. C.S.

(Continued from p. 96).

Some very interesting experiments were instituted in the United States, in 1857, 8, and 9, by Major Rodman, who registered the pressures exerted in a gun on the explosion of a charge, by means of an ingenious instrument, well known as Rodman's Pressure Piston, which has since been extensively employed in similar experiments in France,

* A Lecture delivered to the Members of the British Association at Edinburgh, August, 1871.

moment when a shot passes certain points in the bore. A series (eight or more) of thin metal disks, 36 inches in circumference fixed upon one horizontal shaft, are made to revolve very rapidly, by means of a heavy descending weight through a train of multiplying gear.

A stop-clock, which can be connected and disconnected at pleasure with one of the revolving shafts of the machine, serves to determine the precise rate at which the circumferences of the disks revolve. This is about 1200 inches per second, so that one inch represents the 1200th part of a second; and as, by a vernier attached to the instrument for the purpose of reading the results, an inch can easily be divided into 1000 parts, it is evident that the instrument is capable of recording differences of time less than one-millionth part of a second.

Upon the discharge of the gun, which is placed in connection with this instrument, the exact moment when the shot passes a particular point in the bore is recorded on one of the disks during the time that these are revolving at the speed just mentioned. The manner in which this is accomplished is as follows:—At definite distances from each other a number of hollow steel plugs, corresponding to the number of disks of the chronoscope, are screwed into holes drilled in the gun to receive them. Each of these plugs carries, at the end which is screwed in as far as the bore, after the gun is loaded, a steel cutter, which projects very slightly into the bore, and is held in position by a fine insulated wire, having its extremities protruding at the end of the plug, and therefore outside the gun. Each of these wires is then connected with conducting wires which bring it into circuit with a small voltaic battery, and with the primary wire of a volta induction coil, so that, when this arrangement is complete, a distinct voltaic current circulates through each insulated wire in the gun, and through the primary wire of a distinct induction coil. One end of the secondary wire of these coils is connected with the revolving disks, the peripheries of which are covered with strips of white paper coated with lamp-black, and the other end of each secondary wire is connected with a well insulated pointed discharger, there being one of these fixed in front of each disk, with its points adjusted so as to be just clear of the edge of the disk. When the disks are revolving at the full speed, the rate of which is ascertained by means of the stop-clock, the gun is fired, and as the shot rushes past the cutters which project slightly in the bore, it presses each one in succession level with the surface, and thereby causes it to cut the insulated wire. The primary current is consequently interrupted, and the induced current, which is thereby instantaneously developed in the secondary wire of the coil, passes from the particular discharger to the adjacent disk, producing a minute perforation in the paper at the point where it jumps across to the disk, and burning away the lamp-black at that point, so that a readily discernible mark is thus produced. Supposing it possible that all the primary wires could be severed at one and the same moment, then, as the disks are all travelling at the same speed, the spots which mark the discharge of the induced current upon each individual disk would be in exactly corresponding positions, and would therefore form a straight line across the disks; but as they are severed in succession, the series of spots follow each other upon the several disks—the distance between the spot on the one disk and that on the next being small in proportion to the velocity with which the shot has moved from one point to another in the gun.

Some idea is conveyed of the minute intervals of time which are measured by means of this chronoscope, by the fact that the distances between the parts of the 10-inch gun at which the time-records are obtained are in some distances only 2·4 inches, while the total time the projectile takes to reach the muzzle of that gun (a distance of 100 inches) when fired with a battering charge, is about the one-hundredth part of a second.

It will be seen from the foregoing outline of the nature and employment of this instrument, that by its means the

time is recorded which the shot occupies, from the commencement of motion, in reaching different parts of the gun's bore; from these time-records are deduced the velocity with which the shot is passing through different parts of the bore, and the pressures in the gun which correspond to the velocities. With the aid of this instrument, and the crusher gauge employed simultaneously with it, the Committee on Explosives have compared the action in the gun of the powders hitherto used in the service with several gunpowders of foreign manufacture, and particularly with certain descriptions of powder which have been specially manufactured for employment in large charges. Guided by the results obtained, they have succeeded in producing a description of gunpowder (known as "pebble-powder") the physical and mechanical characters of which have been so adjusted with reference to one another, that the capabilities of large guns have become more thoroughly developed, and their powers of endurance at the same time much less severely tried, by its employment, than by that of any other descriptions of gunpowder which have been specially devised with those objects in view during the last four years. As regards the size of its pebble-shaped masses, this powder bears great similarity to one of the earlier experimental powders tried by the Gunpowder Committee (in 1859), which served as the starting-point in the development of pellet-powder; but it presents important differences in respect to density, hardness, and uniformity of form of the masses, and it is to the combined influence of these points of difference, in reducing the rapidity with which the pressure is developed in the gun, that pebble-powder owes its efficiency.

A comparison of the results arrived at, by means of the chronoscope and a 10-inch gun, with the powder hitherto used in all rifled cannon, known as R. L. G. powder, with the Russian prismatic powder (which for a time was regarded as superior to all other varieties), and with pebble-powder, at once demonstrates the superiority of the latter. The prismatic powder is shown by these results to light very slowly in the gun, and afterwards to burn rapidly, though not so rapidly as the R. L. G. powder. The slow lighting appears to be due to the fact that the prisms have a very hard and difficultly ignitable coating, which has been produced by the concentration of some of the saltpetre upon the surface of the masses, consequent upon the powder containing when pressed a considerable proportion of water, which, in evaporating, draws the saltpetre towards the exterior of the masses. The subsequent rapid burning of the prismatic powder is due to its comparatively low density. The old R. L. G. is both a rapidly inflammable and a very quick-burning powder when used in large charges, on account of the small size of the particles and their comparatively low density; while the large particles of the dense and comparatively hard pebble-powder light somewhat slowly, and also burn slowly as compared with the others. It should be mentioned that pellet-powder, of comparatively low density, as hitherto made for the service, approaches R. L. G. in the rapidity of its explosion when used in large charges, but that, when its density is assimilated to that which has been found most suitable for pebble-powder, it yields results similar to the latter, and there is little doubt that pellet-powder, with this modification, will prove interchangeable with pebble-powder. A comparison of curves, representing the velocities and pressures obtained with pebble, prismatic, and R. L. G. powders, in different parts of the gun, as deduced from the chronoscope results, shows that the velocities of the two first commence by being considerably below that of R. L. G., but that they gradually reach and pass it, the shot leaving the gun at a very considerably higher velocity (that of the pebble being the greatest). These curves also exhibit most important differences with regard to the pressure, the maximum being considerably greater with R. L. G. than with the other two, while the area of the pressure is much greater with these than with R. L. G. It should be stated that in ex-

periments instituted with the 10-inch gun, and even with the 12-inch 25-ton gun, the pressures recorded by the *crusher gauge*, which has been referred to, agree very well with the pressures deduced from the chronoscope results when pebble, prismatic, or pellet powder is used; but that, when R. L. G. or the old L. G. cannon-powder is employed, very considerable and perplexing anomalies are observed, not only between the results of the two methods of experiment, but also between the individual results furnished by the crusher gauge, applied in one and the same round in different parts of the powder-chambers. These anomalous results have been carefully discussed by Captain A. Noble, in a discourse recently delivered by him at the Royal Institution. The scope of the present Lecture does not permit of a full examination of their probable cause; it may, however, be stated that they appear to be due to a wave-action which is set up in the gases, consequent upon the *vis viva* acquired by these, especially with a rapidly-burning charge, before the shot begins to move in the gun, the *vis viva* being re-converted into pressure at the seat of the shot, and thus giving rise to intense local pressures for exceedingly minute periods of time. It has been shown in the course of the Woolwich experiments that, even with the slow-burning powders, pebble and pellet, when the charge is ignited at the point farthest from the shot, or when the cartridges are greatly increased in length, these intense local pressures, observed with the quick-burning powders, are also developed—a result which is greatly in support of the view that they originate in the *vis viva* acquired by the products of explosion, due to the distance which these travel before they are checked by the shot. An experiment made by Robins, in which he placed a bullet sixteen inches away from the ordinary charge in a musket-barrel, and bulged and burst the latter near the seat of the shot by the explosion, leads to the same explanation; and many anomalous results obtained with the Rodman pressure-gauge are obviously also ascribable to the *vis viva* acquired by the gases in the cylinder before they reach the piston which acts upon the cutter at some distance from the bore of the gun.

These somewhat perplexing results have been referred to mainly to show that although great advance has been made in the subject of the adaptation of powder to the ordnance of the present day, much still remains to be done before all conditions are understood which have to be fulfilled in the production of gunpowder thoroughly suited to different guns. There is little question that a powder which is in all respects most suitable for a 7-inch gun will not be equally efficient when applied in a 10-inch gun, and, most probably, the theoretically correct system of meeting the requirements essential to the safe development of the full powers of guns of large size would be the preparation of a special powder for almost every calibre of gun. The practical objections to such a course are, however, obviously insurmountable; hence the result to be aimed at is, the production of a powder which, while fairly utilising the powers of the smaller of our heavy guns, may be safely applied in such charges as are calculated to develop the full value of the largest ordnance.

By the employment of pebble or pellet powder, as now manufactured, not only is the strain upon the guns, up to that of 25 tons, greatly reduced, when velocities equal to those furnished by the R. L. G. powder are attained, but we are, moreover, enabled to obtain from these guns very considerably increased effects without submitting them to a greater strain than they would be exposed to in employing the former service powder to obtain the standard results. But in passing from the 25-ton gun to that of 35 tons, which is designed for a 700-lb. projectile, and a very much heavier powder-charge than has hitherto been used, the satisfactory results furnished by the new powder in other guns are less readily attainable, and it is still uncertain whether, and if so, in what way, further modifications in the manufacture will have to be introduced to meet the requirements of the largest guns. The more

searchingly the nature of the action of fired gunpowder is investigated, and the more the methods of investigation are varied, the sooner, and the more readily and completely, may we hope to fulfil those conditions in its manufacture which will thoroughly establish its efficiency when applied to ordnance of all calibres. The subject is at present receiving in several quarters the careful study and practical investigation which it merits; and before passing to other topics which have to be discussed in this lecture, attention must be briefly directed to a special line of investigation now being pursued by Captain A. Noble, which promises to throw important additional light upon the nature of gunpowder as a propelling agent.

Count Rumford's early attempts to determine the pressure of fired gunpowder by exploding very small charges in a confined space, and experiments of a similar nature instituted some time afterwards by Major Rodman, have already been noticed. The conclusions to which these two experimenters were led by their results, as regards the pressure exerted by gunpowder, differed greatly from each other, and also from the conclusions arrived at in 1857 by Bunsen and Schischkoff, after an elaborate experimental investigation into the nature of the transformation which powder undergoes upon explosion, and of the heat developed when powder is fired in a close chamber. The latter was estimated at 3340° C., or 5980° F., and the pressure which they deduced from their experimental data as the maximum which powder can attain in a closed vessel was about 4374 atmospheres, or about 29 tons in the square inch. This result is no doubt nearer the truth than the estimates made by earlier experimenters; but recent experiments, which will be immediately referred to, appear to have shown conclusively that Bunsen and Schischkoff's estimate of the pressure of fired gunpowder is considerably too low, just as that of Piobert, which is founded upon the assumption that the *solid* products exist as vapour at the time of explosion, and is fixed at about 64 tons (or 9600 atmospheres), is regarded by many as considerably too high. Berthelot, who, like many other eminent scientific Parisians, was impelled by the exigencies of the period, during the recent ever-memorable siege of Paris, to devote his energies and talent to subjects of immediate practical importance connected with the defence of that city, has made an elaborate theoretical investigation into the force exerted by different kinds of gunpowder and by other explosive agents. In criticising the deductions made by Bunsen and Schischkoff, from their experiments with regard to the pressure of fired gunpowder, he points out that they have greatly under-estimated the latter, because they neglected to take into account the effect of the enormous amount of heat liberated by the compression of the gases when powder is exploded in a confined space; in other words, because the temperature of combustion was calculated upon a volume equal to that of the gases measured at zero and at normal atmospheric pressure, instead of upon a volume equal to that of the powder itself, to which volume the gases are obviously condensed when powder is exploded in its own space. He discusses the probable influence upon the pressure exerted by the dissociation of the gaseous products of explosion, at the very high temperature developed at the time of their generation; the counteracting influence of the pressure to which the gases are subject; the cooling effect of the expansion of gas while the shot is being propelled from the gun; and the probable consequent continual disengagement of heat, resulting from new chemical combinations which were not compatible with the original high temperature. The estimate which Berthelot is led to form of the pressure of fired gunpowder is not far below that which Rumford arrived at; thus, he gives the pressure of war-powder, exploded in its own space, as 62,700 atmospheres, an estimate about fourteen times greater than that which Bunsen and Schischkoff based their analytical data upon. His conclusions are not as yet borne out by experimental results.

The analytical examination instituted by Bunsen and

Schischkoff of the products of explosion of gunpowder dispelled the confidence up to that time entertained in the old theory of the chemical change of gunpowder, which assumed, as already stated, the conversion of the carbon into carbonic acid, or carbonic oxide, or both, and the conversion of the sulphur into potassium sulphide. According to their analyses, the largest proportion of the sulphur is oxidised to sulphuric acid potassium sulphide being one of the smallest products of the change. While there is no doubt that the old theory of the decomposition of powder is very wide of the actual truth, it is generally considered that the method pursued by Bunsen and Schischkoff in burning gunpowder, with the view of collecting the products for analysis, was not calculated to furnish results fairly representing those which would be obtained by exploding gunpowder in a closed vessel, as in the chamber of a gun. Some experiments, subsequently made by Karolyi, in which he exploded very small charges under conditions more nearly approximating to those of the actual employment of gunpowder, furnished analytical results not very greatly at variance with those of Bunsen and Schischkoff, but the value to be attached to them appears likely to be definitely determined before long by the experiments upon which Captain A. Noble is at present engaged. In iron vessels of great strength he explodes, by electric agency, charges of gunpowder ranging up to 2 pounds; the space in which the charges are fired is varied from that entirely filled by the powder to that in which the latter occupies only 10 per cent of the space, and the vessel is fitted with a crusher gauge, by which the maximum pressure developed by the explosion is recorded. The gases are in all instances entirely confined, and are allowed to escape gradually, as soon as expedient, after the explosion, with a view to the measurement of their volume and the collection of portions for analysis (their examination and that of the solid products having been undertaken by myself). It would be premature to enter upon any account of the analytical and other results furnished up to the present time by these experiments; it may be stated, however, that the maximum pressure of fired gunpowder, unrelieved by expansion, has been found to be about 40 tons to the square inch, and that an examination of the relation between the tension and density of the powder-gases, obtained in a closed chamber, furnished results closely corresponding with those deduced from the observation of the tension of gases in the bores of guns, made by the Committee on Explosives.

The imperfect outline which has been given of the investigations, both scientific and practical, which have been instituted during the last two or three years, and are still in progress, will suffice to show that these have not merely an important direct bearing upon requirements which the recent great progress in the construction of artillery has created, but that they are also contributing largely to the attainment of more correct and precise information with regard to the action of gunpowder when exploded in a confined space, and the operation of the various modifying influences which may be brought to bear upon it.

(To be continued).

FACTS DEVELOPED BY THE WORKING OF HEMATITE ORES IN THE ULVERSTONE AND WHITEHAVEN DISTRICTS, FROM 1844 to 1871.* By THOMAS AINSWORTH.

I MUST preface the remarks I am permitted to make to you to-day by drawing your attention to the *Report of the Proceedings of the British Association for the Advancement of Science*, 1870, pp. 9 and 10. You will find there the

* Read before the British Association, Edinburgh Meeting Section B.

following letter from Professor Stokes on the part of the committee appointed at Exeter to confer with Her Majesty's Government as to the completion of the investigations into the composition and geological distribution of the hematite iron ores of Great Britain and Ireland.

"To the Rt. Hon. the EARL DE GREY AND RIPON,
Lord President of the Council on Education.

"Lensfield Cottage, Cambridge,
"December 17th, 1869.

"My Lord,—I have the honour to inform your Lordship that, at the last meeting of the British Association for the Advancement of Science a resolution was passed appointing a committee for the purpose of calling the attention of Her Majesty's Government to the importance of completing without delay the valuable investigation into the composition and geological distribution of the hematite iron ores of Great Britain and Ireland, which has been already in part published in the *Memoirs of the Geological Survey*. Your Lordship is doubtless aware of the remarkable process invented some years ago by Mr. Bessemer for the conversion of crude cast-iron into steel or wrought-iron, a process by the application of which, those important materials can be manufactured at a much cheaper rate than formerly. The royalty which at present exists on iron, to which the Bessemer process has been applied, will shortly expire, and its expiration will probably give a great impetus to the iron trade of the country.

"It is not, however, every iron ore that ironmasters have been in the habit of employing which can be used for the production of cast-iron destined for conversion by the Bessemer process—for there are certain impurities which that process fails to remove, and which are extremely injurious to steel or wrought-iron. This difficulty is got over by preparing the iron from hematite, an iron ore which is free from those impurities. Accordingly, on the expiration of the Bessemer royalty, a great demand for hematite is likely to arise, and it will be important for the iron trade of the country that it should be known where hematite is to be found. For many of the counties of England the requisite information is contained in the *Memoirs* referred to in the resolution quoted above, and the object of the British Association is merely to urge on Her Majesty's Government the importance of continuing and completing without delay the investigation thus so ably begun.

"Although the application of the British Association relates to trade, I have addressed myself to your Lordship rather than to the President of the Board of Trade, because it is to be presumed that the investigation would be best completed by the same body by which it was begun, viz., the staff of the Geological Survey, and that belongs to the department over which your Lordship presides.

"The committee will be ready to wait on your Lordship should you think a personal interview expedient. The committee consists of Professor Harkness, President of the Geological Section at the Exeter Meeting of the British Association; R. Godwin Austen, Esq., F.R.S., Vice-President, and myself."—I have the honour to be, &c.,
G. G. STOKES.

To this application the following reply was received:—

"Science and Art Department, London, W.
"February 8, 1870.

"Sir,—Your letter to the Lord President of the 17th of December, 1869, stating that at the last meeting of the British Association for the Advancement of Science a resolution was passed appointing a committee for the purpose of calling the attention of Her Majesty's Government to the importance of completing without delay the valuable investigation into the composition and geological distribution of the hematite iron ores of Great Britain and Ireland, which has been already in part published in the *Memoirs of the Geological Survey*, has been under the consideration of the Lords of the Committee of Council on Education.

"I am directed by their Lordships to inform you that, after consulting with Sir Roderick Murchison on the subject, they have come to the conclusion that they are not in a position to direct that the former investigation shall be continued by the officers of the Geological Survey.

"The investigation referred to was not made at the public cost, and it does not appear to my Lords that a special inquiry of this nature, involving considerable additional expense, falls within the object for which the sum voted by Parliament for the geological survey has been granted. I am, Sir, your obedient servant,

"NORMAN McLEOD, Assistant Secretary.

"To Professor Stokes, M.A., F.R.S.,

"Lensfield Cottage, Cambridge.

I quite agree in all that has hitherto been done in this matter—that is, in the application to the Council on Education, for I think that to it and not to the Board of Trade this application should be made, but I quite agree in the view taken by the Council on Education, fortified as it is by the opinion expressed by the venerable and respected member of this association, Sir Roderick Murchison, and I hope the day is far distant when, as a nation, we are to ask for Government aid and assistance in every little difficulty, for, were it granted for the asking, the Anglo-Saxon characteristic of self-reliance would soon be undermined, and the English, while they lost the reputation of being a nation of shopkeepers, might probably obtain that of waiters on Providence incapable of private enterprise.

Now I do not profess to be either a geologist or a chemist, but merely an owner and worker of hematite iron ore mines for nearly thirty years, an observer and recorder of some facts which my locality has presented to me, and which the kindness and intelligence of friends in other districts whose names I shall introduce to you have enabled me to verify from their longer experience. I shall speak of facts and not of theories, and I must premise that I shall refer to rocks and formations only by their common names and in their widest acceptations, and not according to the particular and minute classifications of the geologist.

The facts which I wish to bring before you came to my notice in the following order. When I came to reside in West Cumberland, a friend of mine had opened a colliery in the parish of Cleator, the proceeds of which were larger than could be disposed of in the neighbourhood, and hematite ore having been worked in the district to some extent for many years and exported to Wales, Scotland, and other iron-making countries, it seemed to us a reasonable speculation to retain the ore in the country and use it with the surplus coal. A company was formed to build furnaces on a site adjacent to the colliery; limestone and hematite iron ore being in close proximity thereto. These furnaces are the present Cleator Moor furnaces, belonging to the Whitehaven Hematite Iron Company. Limestone, as I before said, adjoined the site, and the owner of the limestone quarry was at first quite willing to sell us at a reasonable price what limestone we required for smelting, but finding the demand increase, he raised his prices so much as to place us in an awkward position. Believing that I had limestone in my own lands which adjoined this quarry, we commenced boring, and soon found the limestone at no great depth. Our neighbour then became amenable to reason, and my limestone was no longer needed, but being down at the limestone we thought we might as well bore a little farther. However, a kind friend one fine night dropped the boring chisel point upwards into the hole, and we were stopped. There is always some reason for every thing, and not knowing I had any enemies, it occurred to me that it was, perhaps, some iron ore raiser who did not wish his trade to be interfered with like our lime customer, so I determined to renew my boring, but, instead of going to fathoms to the limestone, I preferred coming to what I thought might be the outcrop of the lime and boring there. I did so, and at 7 fathoms came not on limestone, but on ore without any rock cover. This was at variance with the accepted theory that hematite iron ore was confined to

the limestone, and this theory having been once found wrong, it caused me to doubt its general accuracy, and I have since found that hematite iron ores do not, as a rule, confine themselves to any particular rocks, but are found sometimes without any rock cover at all, as in my case. Sometimes in limestone fissures, as frequently in the Cleator district; sometimes in slate fissures, as at Knockmorton; sometimes in granite, as in Eskdale; sometimes in what we call whinstone, but very frequently between two different rocks, *i.e.*, slate rock on one side and limestone on the other, as at Lindale Moor and Park Mines in Furness—whinstone on one side and limestone on the other—sandstone on one side and limestone on the other, as at Lord Leconfield's Big Rigg mines; and sometimes in a fissure in trap, as at Hading, so that it can be said to belong to no particular rock, which is the first fact I have noted. The second fact which presented itself to my notice was that the hematite iron ore formation must have some relation to the coal fields, for as the development of the iron ore mines proceeded, we found that the chimnies of the iron ore pits took the outer range of the coal pit chimnies. By outer range I mean a line further from the sea than the coal, but nearer to the mountain range and the outcrop of the metals. This fact, however, was quite at variance with the hematite iron ore field in the Ulverstone district where there never was a trace of coal.

However, some years after, Mr. Kennedy, of Ulverstone, boring near the entrance to the Duddon estuary, came on what he called drift-coal lying in the running sand. Small though these pieces of coal were, they gave their voice in favour of the vicinity of the coal formations; and this has now distinctly and unmistakably announced itself by the exploration at Sturch, near Barrow, to the south of the previous workings, where Mr. Wadham, as mineral agent for the Duke of Buccleuch, has just opened out and taken to a depth of 97 fathoms a pit commenced nearly 200 years ago as a coal-pit, and which Mr. Wadham continued to deepen as a coal-pit till he came to a mass of hematite iron ore worthy of his perseverance. A section is on the wall, kindly provided by him, and will be explained by him.

In addition to this, you will find a section of the Montreal Iron Ore pit in the Cleator district, provided by another kind friend, Mr. Turner, passing through coal strata, and at last developing itself in hematite. This confirms my second fact, that all large hematite deposits are associated with a coal-field.

The third fact which we have chronicled in the Whitehaven and Ulverstone fields is, that these hematite deposits seem to run from north-west to south-east, as if they had some relation to the magnetic current. You will observe, on the index behind me, the red line denoting magnetic north and south,—and I will put upon it by the black pointer the direction of the hematite deposits in the Ulverstone, the Whitehaven, and the Haddington districts, and you will find that they have all a persistent tendency to take a north-west and south-east direction. To such an extent is this fact accepted in the Whitehaven district, that, whenever a deposit is struck in one property, the owners of adjacent royalties bore upon the well-known direction. Mr. Roper, a most valued correspondent, speaking of the Ulverstone district, says that if you take an ordnance map, and start from the line of their open workings (those of Messrs. Harrison, Ainslie, and Co., of Lindale Moor), you may, with a parallel ruler, get the line of every other vein in the district.

There is yet another point bearing on the magnetic correlation. I found, in testing borings, that what the magnifying glass did not reveal the blade of a knife would, and many times, when it was difficult to decide, even from the specific gravity, whether there was iron ore in the borings or not. The magnetised blade of a knife would do it; for it would attract particles of iron from the mass, just as a magnet attracts the iron filings from a mixture of brass and iron filings. Now I leave this matter in the hands of the electricians. We know a little,—but very

little,—of the magnetic current; we know it is constant,—that electricity applied to the magnet intensifies its power almost incalculably. Can this constant magnetic current weaken or dislocate the rocks in its course, and thus prepare a channel for any hematite deposit which may take place from the coal-fields? There is an affinity, but I am not prepared to say which is cause and which effect.

The fourth fact is the almost total want of carbonic acid in hematite deposits, and the vast amount of carbonic acid in the iron-stone deposits in coal-mines. This, I leave to the chemists. On the table you will see an extract from the *Memoirs of the Geological Survey of Great Britain*, and you will there find that, while the hematites give no certain return of carbonic acid, the iron-stones in all the coal-measures hold it in large quantities. The question naturally arises,—Can the chemist, by his art, reduce the iron deposit of the coal-measures to a hematite, and how would he do it? Having obtained a hematite, could he *resolve* it?

The fifth fact is that I know of no hematite deposit of any size or magnitude which is not bordering on a coal-field, and that coal-field at its dip under the influence of water. I refer you to the maps on the wall, and ask you to notice how the Furness district, the Whitehaven district, and the Haddington district have all that singular characteristic. I merely give it for what it is worth, but it is a fact. The Bristol field I have not examined myself, and therefore I say nothing of it, but I believe it has the same conformation; and I am told the hematite lodes have the same direction—south-east and north-west; but, as I do not know of my own knowledge, I say nothing about it.

There is, perhaps, one other circumstance attending the Ulverstone and Whitehaven fields which I ought to name, as otherwise, confusion may arise when we speak of hematite iron ores. The trade in general, the raisers as well as users of ore, speak of two kinds of hematite, rock, or blast ore, and smil, or puddle ore. The first is got with steel jumpers, double-handed hammers, and gunpowder; the second, or soft ore, with picks and shovels. Now, to all appearance, this latter ore is deposited by filtration, and the former has not this. The mines in Furness, until recently, were all of the former character. On the table, you will find a specimen of the soil from a field near Furness Abbey; and it is a fact that iron ore is re-deposited by filtration after the lapse of a few years.

Thomas Ainsworth, August 2, 1871.

ON J. STODDART'S PLAN OF CONCENTRATING SULPHURIC ACID: REPLY TO F. BODE.

By JOHN GALLETTY.

WHILE engaged on some work for Mr. Young, at Bathgate, now fully two years ago, the idea of concentrating vitriol with the aid of a current of air in lead vessels suggested itself to me, and I made some experiments on the subject, which, being done entirely independent of those of Mr. Stoddart, a short account of my results may be interesting, in addition to any facts Mr. Stoddart may communicate.

I repeatedly concentrated a gallon of brown vitriol in a small lead box, the depth of the liquid being 4 or 5 inches,

* Highest. † Lowest.

and the temperature varying from 190° C. to 200° C., till the specific gravity was about 1.840. In these experiments I chiefly examined the lead box, and compared the appearance of the precipitate of sulphate of lead which this vitriol gave on dilution with water, with that from the same vitriol concentrated in glass bottles, and felt satisfied that the action on the lead was but slight, and would not be a practical difficulty with vitriol made from sulphur, although it might be with pyrites vitriol.

I have, however, a note of one experiment more definite. I used a lead box, 18 inches long by 12 inches broad, and had a lead shelf burnt in it, the full breadth and nearly the whole length of the box, at such a height that, when just covered, the box held 5 gallons. Below this shelf a lead pipe with small holes in it was introduced, through which air was forced, which passed along under the shelf and about an inch from the surface of the vitriol; it was the same arrangement that Mr. Young employed for saturating his solutions with chlorine in the manufacture of chlorate of potassa. In this apparatus I prepared from brown vitriol (1.745 sp. gr.) 5 gallons of vitriol, of 1.830 sp. gr., by keeping the temperature at 205° C. for one hour, and forcing 16½ cubic feet of air through the liquid. The loss of monohydrated sulphuric acid was 11.19 per cent, as against 8.8 per cent, which I found to be the loss by concentrating in the ordinary glass bottles; this, however, could be recovered by passing the air into the chambers or through a condenser. The quantity of air used in this case will appear small; it was only roughly measured by blowing air through the same lead pipe into a gas-holder in as nearly the same manner as possible, but, having a note that 24,000 cubic feet of gas was forced into a gas-holder by fanners, against a pressure of 5 to 6 inches of water, with the expenditure of 1 ton of coals, it did not appear necessary for my purpose to be more exact.

The water that came away at first contained practically no vitriol; the last fourth had a sp. gr. of 1.070. The object of my experiments was chiefly to effect the concentration of vitriol to about 1.840 sp. gr. in lead vessels at a temperature not higher than is usually reached in making brown vitriol (1.745 sp. gr.). I felt satisfied that the dissolving of the lead pans by the ordinary method of concentration was due much more to the increase of temperature required to expel the water from brown acid than to the action of the stronger acid on the lead, and my experiments confirmed me in this belief. I have not since, however, had an opportunity of carrying out this process on a working scale, although it has been the intention to do so at Addiewell for some months past. I have no doubt of the process succeeding, but must add that Mr. Napier, of Glasgow, aware of my results, did commence to give it a trial some time last year, without at once getting it to succeed. I understand his box did not keep its shape, a difficulty that could be easily avoided, but I have not heard that he has renewed the experiment.

Theoretical calculations of the advantages of this plan of concentrating vitriol, though not to be neglected, can only be wide approximations to working results. So much heat from even the best built pans passes into the flues that there is ample to spare for superheating the air and propelling a small engine for blowing it through the vitriol. Again, if the water can be evaporated at a heat lower by 80° C. by using a current of air than without it, the extra heat, communicated to the vitriol in consequence from the furnace, will be very considerable, but varying with each construction of furnace. Then, in the case of the concentrated acid, the heat would be communicated by direct contact with the lead vessel, whereas, in the ordinary glass bottle, it is radiated to the vitriol from the hot sides of an iron pot. The labour of filling and emptying so many bottles with syphons, and attending to so many fires, would also be avoided. It seems to me as if concentrated acid might almost be sold at about the present price of brown, allowing for the difference in strength.

Addiewell Chemical Works,
August 24, 1871.

NOTICES OF BOOKS.

The Elements of Plane and Solid Geometry. By H. W. WATSON, M.A., sometime Fellow of Trinity College, Cambridge, late Assistant-Master of Harrow School. London: Longmans, Green, and Co. 1871.

In this, the sixth of a series of scientific handbooks published by Messrs. Longmans, Mr. Watson opens up new ground for the student of geometry, and, by an original method of treatment, makes Euclid much more comprehensible. The syllogistic form of enunciation has been retained, but with an extension of the principle of superposition, whereby much unnecessary reasoning has been dispensed with. The work is certainly to be highly commended to the student's notice.

Useful Chemical Tables, arranged for the Use of Teachers and Students. Oxides, Sulphides, and Chlorides, with Blank Forms for adaptation to other Compounds. By ADOLPHUS COLLENETTE, Teacher of Chemistry, Elizabeth College, Guernsey. Guernsey: F. Clarke. 1871.

THESE tables will be useful not only to students, but also to teachers of chemistry; they are intended—(1). To give a tabular view of the principal binary compounds of the elements with O, S, and Cl; (2) to give, at a glance, the number of compounds of any element with the metalloids just mentioned, and the number of oxides, sulphides, or chlorides having one formula. By means of the blank forms, the following compounds may be tabulated:—Iodides, bromides, fluorides, oxychlorides, oxybromides, oxyiodides, acids, &c. The author has adopted two methods of classification, viz.—(a) Quantivalence: the elements being classified under the heads Monads, Dyads, Triads, &c.; (b) Metalloids and Metals: the former are printed in red type, the latter in black, while thick type is employed for common metals and italics for rare. We have great pleasure in recommending this volume to all who are interested in having the study of chemistry simplified and methodically treated, as well as to chemists generally, not only as tables of easy reference for existing compounds, but also to register new discoveries. The typographical execution of these tables is highly creditable to the press of the Channel Islands.

MISCELLANEOUS.

An American View of Patent Laws.—The Hon. Charles Mason, an eminent Ex-Commissioner of Patents, has written to Mr. G. Haseltine, M.A., Chairman of the Meeting which passed the Resolutions on "Patent Law Reform," reported by us July 7th, an instructive letter on the subject, an abstract of which we append:—I have, he says, never had any serious doubt of the wisdom of a judicious system of patent laws. The public welfare is best promoted by inspiring individual effort in respect to invention, through the motive of private gain; and who can more justly claim the exclusive use of any property than he who has brought it into being?—The American system of examination is productive of much advantage to inventors and the public, but I doubt the wisdom of lodging in officials an unlimited power of rejection. If the duties of examiners were advisory and adjuvant, reserving to an applicant the ultimate right to a patent, at his own risk, the chief objection to this system would be removed. The fees by all means should be small—barely sufficient to defray the expenses of the patent office. Inventors are benefactors, and, as a class, poorly compensated for their labour. The imposition of large fees discourages invention, and thereby checks the progress of civilisation. This cannot be sound policy. Experience leads me to the conclusion, that patents should be granted for more than fourteen years, but this term, in most cases

of merit, is extended by our office to twenty-one, and often by Congress to twenty-eight years. The new law limits the term of a patent to seventeen years, which will, no doubt, hereafter be extended; and I do not think twenty-one years too long a period for the original grant. In one respect I like your system better than ours—your fees are paid in instalments, giving the patentee the option of keeping his patent alive. The French plan of annuities is carrying the matter rather too far. I think the English system better than the French or the American, and all that is needed is a reduced rate of fees. Experts are often very useful, but they are regarded with suspicion, and their opinions have little weight in our courts, therefore, what might be a great evil, carries in some measure its own remedy, and the interposition of jurors in patent suits is generally avoided by obtaining injunctions in chancery, which is our usual remedy for infringements.

Prosser's Spreading Fire Nozzle.—There is no greater enemy to life and property than fire, and although of late years the subject of fire-engines has received great attention from practical men, yet there is great room for improvement in detail. We have therefore great pleasure in calling the attention of manufacturers, warehousemen, mill-owners, railway companies, ship-owners, theatrical managers, &c., to "Prosser's Adjustable Spreading Nozzle." Yesterday evening we were invited to see this nozzle tried in practice, Mr. Holland, proprietor of the North Woolwich Gardens, having previously made arrangements for the attendance, with their engines, of three of the London Volunteer Fire Brigades—namely, the Wood Green, Pentonville, and the Ferdinand Volunteer engine from Camden Town, the whole under the superintendence of Mr. Reiney. Mr. Prosser welcomed the opportunity of showing the public what his nozzle could do; before being fitted on to the ordinary branch pipe of a fire hose, the structure was explained to us. It consists of a nozzle fitted with a number of movable and an equal number of fixed fingers. The movable fingers may be brought into the stream issuing from the jet, thus dividing the solid stream into a more or less fine spray. This is done by a simple turn of the wrist. The result of this ingenious mechanism is that the stream of water can be cut up into a spray more or less fine: thus at one time there were playing from the nozzle eight of the adjustable fingers, at another time ten, at another time four, the stream being finally varied from one resembling in its intensity a thunder shower to the ordinary spray of a shower bath. A wooden house had been built at one end of the North Woolwich Gardens, and between the walls were piled tar-barrels, timber, and other inflammable materials; shortly after a light had been applied the whole place was in flames; a signal was then given to the fire-engines to play upon them. Standing close to the fireman who had the working of Mr. Prosser's patent nozzle, we were enabled to watch its action narrowly. A stream of water first issued from it as from the nozzle of an ordinary fire-engine. The fireman then, by a slight turn of the wrist, altered the form of the jet at will according to the force of water he wished to bear on the fire. The conclusion that we have arrived at is, that Prosser's spreading nozzle is a valuable adjunct to the present known means of extinguishing fires, for by setting the internal mechanism at work the fireman is enabled to approach the flames when at their fiercest; as they gradually subside so he alters the form of his jet. In close quarters a good blaze has no chance whatever against the nozzle, for the water is spread out into a large shower of heavy rain in a conical form, or the jet may be so adjusted as to rush out like a vapoury tail of a comet. The water being thus thoroughly subdivided is formed into spray, every drop of which coming into contact with the heated materials, is immediately converted into vapour, against which the flames can no longer hold their own. It is at the commencement of a fire that assistance is most needed, quickness of action in extinguishing the

origin of the fire being all essential. We therefore recommend all those who have already either engines or hose fitted, to procure one of these spreading nozzles, which we understand are adaptable to any branch as at present fitted, as they appear calculated to become the means of preventing the loss of much valuable property.—*Land and Water.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 7, 1871.

The original papers and memoirs met with in this number and relating to chemistry and collateral sciences are the following:—

Production, by Artificial Means, of the Calcareous Matter such as is met with in the Animal Organism.—M. Harting.—This paper is a preliminary communication on the subject alluded to, which may be termed a first attempt at synthetical morphology. It appears that the author has obtained results of great importance, which will be communicated at a future day in full, accompanied by engravings of the specimens, some of which have been sent to the Academy.

New Book on Applied Geology.—E. de Beaumont.—As one of the perpetual secretaries, the *savant* just named calls the special attention of the meeting to "*Leçons Élémentaires de Géologie Appliquée à l'Agriculture*," by M. Meugy.

Spectra of the Simple Gases.—A. J. Angström.—A lengthy monograph on this subject.

Calorific Phenomena which accompany the Conversion of Hypo-nitric into Nitric Acid, and on the Introduction of these Two Acids into Organic Substances.—L. Troost and P. Hautefeuille.—The contents of this paper bear upon calorimetry, and cannot be usefully abstracted without the reproduction of lengthy series of tabulated results of experiments.

Accidental Kindling of a Gas Burner by Lightning.—W. de Fonville.—During a thunderstorm at Paris on the 3rd of August last it appears that a building in the Rue Leclercq was struck by lightning, and that the gas of a gas burner placed close to a wall and near to a metal water-pot, was ignited by the electric spark.

This number also contains several papers relating to meteorology and geology.

Le Moniteur des Produits Chimiques pour l'Industrie, les Sciences et les Arts et du Matériel de ces Industries Publié par une Société de Chimistes et d'Industriels, Nos. 1 and 2, 1870.

This periodical, published at Paris, made its first appearance just before the war broke out last year. Only two numbers appeared then, but the publishing having been now resumed, we shall be enabled to communicate to our readers any useful or interesting original matter which may be met with in the pages, of which the full title is given above. This paper appears on the 10th and 25th of each month.

No. 3, July 10, 1871.

This number contains the following original papers and memoirs:—

Sucrate of Hydrocarbonate of Lime applied to the Refining of Cane Sugar.—MM. Boivin, Loiseau, and Co.—This lengthy memoir is divided into the following sections:—Production of the lime and carbonic acid; slaking of the lime; preparation of the saccharo-calcic solution; formation of the sucrate of hydrocarbonate of lime; utilisation of the sucrate of hydrocarbonate of lime; filtration of the purified liquor; saturation of the filtered and purified liquor; boiling of the saturated liquor; filtration of the liquor after boiling; washing the residues; the chief advantages of the process of the sucrate of hydrocarbonate of lime. The contents of this paper bear essentially upon the practical application of the process alluded to.

Soap Manufacturing Industry of Italy.—E. Rousset.—Contains a few historical and interesting statistical matters on this subject.

Ancient Brevets d'Invention.—Under this title it is proposed to re-publish some of the more important *brevets d'invention* of old date. Very properly, the series is opened by a brevet granted for fifteen years to Nicholas Le Blanc, on September 15th, 1791, for the extraction of soda from common salt on the large scale.

Utilisation of Waste Leather Cuttings which contain Grease.—M. Picard.—During certain processes of the operations known as tawing and currying, leather is impregnated with fatty substances. The waste cuttings are submitted by the author, first to ebullition in water, and next, after decantation of the water, to strong pressure by means of an hydraulic press; the greasy matters are thus cheaply and readily recovered, and may be used for various purposes.

No. 4, July 25, 1871.

The original papers contained in this number are—

Chemical Products of Italy.—E. Rousset.—This paper treats on the following subjects:—Production of acids (viz., sulphuric, nitric, hydrochloric, citric, and boric), alkalies, and salts, including the gunpowder industry in the kingdom of Italy.

Soap Manufacturing Industry at Marseilles.—E. Rousset.—The ancient city just named has sixty-two soap-works, producing, on an average, annually 70,000,000 kilos. (70,000 tons) of hard soap made of olive oil. Although the bulk of this quantity is used in France, a greatly increasing export trade of this article is here spoken of.

New Method of Preparing Borax.—M. Jean.—When an alkaline sulphuret, boric acid, and water act put together, the fluid just named is decomposed; its oxygen combines with the metal, which, as oxide, combines with the boric acid, while sulphuretted hydrogen is set free. This reaction is elucidated by the following formula:— $SM + 2BO_2 + HO = SH + 2BO_2.MO$. The author carries on his process by first preparing sulphuret of sodium from sulphate of soda, which is thrown into a vertically-placed fire-clay retort filled with coke and previously heated to redness. The carbon reduces the sulphate of soda into sulphuret, which runs off at the bottom of the retort (the coke resting on a perforated slab of fire-clay). The sulphuret thus obtained is broken into small lumps, and, having been placed in a stout linen bag, is, along with the boric acid (also contained in a linen bag), suspended in the higher portion of a cylindrically-shaped tank filled with cold water. That tank is fitted with an air-tight cover, wherein a pipe is fixed to carry off the sulphuretted hydrogen.

Obituary.—Under this head we learn that the well-known Dr. Boucherie died lately at Bordeaux; the deceased was widely known by his investigations on the preservation of wood and timber, and was in early life one of the first who manufactured beet-root sugar in France on the large scale. Prof. Fritzsche, of St. Petersburg, died on the 8th ult., at Dresden; the deceased occupied a prominent place among the savants of Imperial Russian Academy of Sciences, and as the discoverer of aniline, not only science, but modern industrial chemistry, owes very much to him. It would be next to impossible to quote here, even briefly, the large number of the deceased's scientific labour.

No. 5, August 10, 1871.

The original papers contained in this number do not bear upon chemistry directly, and are only of local interest.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 210, June, 1870.

This number does not contain any original papers relating to chemistry and allied sciences.

Nos. 211 and 212, July and August (double number), 1870.

The contents of this number are entirely devoted to the publication of the proceedings of the general annual meeting of this Society, the distribution of prizes and medals, and the reports of various committees on divers subjects. The only paper more directly bearing upon chemistry is—

Report on the Prize Essay concerning the Utilisation of Manufacturing Residues.—Prof. Balard.—From this lengthy memoir, not well suited for any useful abstraction, it appears that the best essay on the subject alluded to was sent in by P. Buquet and W. Hofmann—the former manager, the latter chemist to the chemical works at Dieuze. The essay alluded to will be published by this Society.

Nos. 213 and 214, September and October (double number), 1870.

The only original paper met with in this number, and indirectly bearing upon chemistry, is—

Eulogium on Theophile Jules Pelouze.—M. Dumas.—However valuable the contents of this very lengthy scientific biography are, they are not suited for any useful abstraction here.

Nos. 215 and 216, November and December (double number), 1870.

The only original paper relating to chemistry contained in this number is—

Report on P. Thomas's Gas Burner.—M. Debray.—This lengthy paper is accompanied by several woodcuts illustrating a contrivance by means of which it is possible to obtain at pleasure, with the gas burner alluded to, either a far lower or very greatly increased temperature than is possible with the Bunsen burner.

Annalen der Chemie und Pharmacie, July, 1871.

The following original papers are contained in this number:—

Researches on the Constitution of the Doubly-Substituted Benzols.—E. Ador and V. Meyer.—The fourth and concluding instalment of a monograph on this subject, containing the following sections:—Sulphanilic acid; benzol-sulpho acid from sulphanilic acid; from-benzoic acid and isophthalic acid; general review and appendix.

Gallic Acid Ethers.—F. Ernst and C. Zwenger.—This essay treats on the ethers which gallic acid forms, and may be prepared by first dissolving that acid in the respective absolute alcohol, and next passing through that solution, heated to the boiling-point, dry hydrochloric acid gas. The purification of these ethers is rather a tedious process. Gallic acid ethyl-ether—

is a solid substance, soluble in warm water, crystalline, readily soluble in alcohol and ether. These solutions exhibit an acid reaction. This ether fuses at 150°, but at 90° if rapidly heated; it melts in its water of crystallisation. The gallic acid methyl-ether closely corresponds, in its properties, with the foregoing. The gallic acid amyl-ether—

is a solid crystalline substance, contains no water of crystallisation, fuses at 130°, difficultly soluble even in warm water, but readily so in alcohol, ether, and chloroform, which latter does not dissolve gallic acid. All these ethers act as acids, decompose alkaline carbonates, and yield, with prutn-salts of iron, a violet colouration, which becomes blue by exposure to air. With the per-salts of iron a deep blue colouration is produced, while these ethers reduce nitrate of silver and chloride of gold at the ordinary temperature.

Researches on some of the Substances Crystallised in Fused Beads of Phosphor Salt and Borax.—A. Knop.—The continuation of the exhaustive monograph on this subject contains the following sections:—Crystallisations from phosphor salt; crystallisations from borax.

Normal Valerianic Acid.—A. Lieben and A. Rossi.—The acid alluded to is obtained by boiling normal cyanbutyl with alcoholic caustic potassa solution. The purified acid, $C_5H_{11}O_2$, exhibits an odour more akin to that of pure butyric acid than to that of the ordinary valerianic acid. The normal valerianic acid is a liquid which, even at -16°, is not congealed; it boils at 185°; its sp. gr. at 0° is 0.957. 1 c.c. of this acid requires for its solution 27 c.c. of water. The authors describe a series of the salts of this acid.

Researches on the Allyl Group. Seventh chapter: Conversion of Allylic Alcohol into Propylic Alcohol.—B. Tollens.—And on—

Allyl-Cyanide, or Crotonitrile.—A. Rinne and B. Tollens.—And—

Oxidation of Allylic Alcohol.—A. Rinne and B. Tollens.—Are portions of the lengthy monograph on the allyl group. However valuable and interesting in a scientific point of view, this work is not suited for any useful abstraction.

Alleged Bibasicity of Gluconic and Lactonic Acids.—R. Fittig.—A reply to Prof. Hasiwetz's paper (see CHEMICAL NEWS, vol. xxiii., p. 287) on this subject.

Action of Sulphurous Acid upon Platinum-Chloride.—(Second paper).—K. Birnbaum.—After briefly referring to his former paper on this subject (see CHEMICAL NEWS, vol. xx., pp. 189 and 322), the author, in this portion of his essay, describes a series of salts obtained by the action of sulphurous acid upon platinum-sal-ammoniac. The soda salt may be obtained in orange-coloured, silky, shining, needle-shaped crystals; formula—

The lime and magnesia salts are too deliquescent to be obtained in crystalline state. The baryta salt, $3Pt_2Ba_6NH_4_3SO_3.10Cl_3H_2O$, or—

is a crystalline body. The paper further refers to the potassa salt, and a series of double salts belonging to this group.

Temperature of Decomposition of Sulphuretted Hydrogen.—J. Myers.—From the author's experiments it appears that sulphuretted hydrogen is decomposed at between 350° and 400°.

Sulphuretted Hydrogen Contaminated with Arseniuretted Hydrogen.—J. Myers.—At the ordinary temperature the two gases alluded to can co-exist without decomposition, which only takes place at the boiling-point of mercury according to the formula—

The author, while experimenting, thought that the arseniuretted hydrogen might be due to the presence of some arsenic in the sulphuret of iron employed, but, on investigation, it turned out that the source of the arsenic was in the commercial sulphuric acid used for the evolution of the sulphuretted hydrogen.

Journal für Gasbeleuchtung und Wasserversorgung, No. 14, 1871.

The original papers in this number bear strictly on matters relating to gas- and water-works' engineering and management.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, May, 1871.

This number does not contain any original papers bearing upon chemistry, but we meet here with an essay on the—

Velocity of the Progress of Electro-Dynamical Action.—Dr. Helmholtz.—The author found that the velocity alluded to exceeds 314,400 metres (about 195 English statute miles) in one second of time.

Les Mondes, August 17, 1871.

This number contains the following original matter relating to physico-chemical sciences:—

Studies on the Geology, Meteorology, and Archæology of Constantine (Algeria).—M. Tissot.

Sound Produced by Discontinuous Vibrations, more especially those obtained by means of the Siren.—M. Terquem.—The contents of this paper bear strictly upon acoustics.

This number contains a series of papers bearing upon hygiene, and, among these, one on drunkenness among the French soldiers as a cause of the late disasters.

Pharmaceutische Zeitschrift für Russland, No. 6, 1871.

This number does not contain any original papers relating to chemistry.

No. 7, 1871.

The original papers and memoirs relating to chemistry and allied sciences in this number are—

Experiments made to Ascertain the Alleged Poisonous Nature of certain kinds of Fish.—Dr. A. Casselmann.—The contents of this paper bear upon some experiments made upon cats to which was given some fish (properly cooked), which, on being partaken of as food, had caused, in some thirty-five cases, symptoms of a peculiar kind of poisoning. The fish was, however, not quite fresh, but being partly cured with salt, and kept at the winter temperature of St. Petersburg, was not at all in a decayed state. The nature of the poison was not discovered, neither were the cats at all affected by the fish given to them, which, in this instance, belonged to the sturgeon tribe. It is a well-known fact that fish may become poisonous under conditions as yet entirely unknown.

Means to Distinguish Benzol from Benzine.—J. Brandberg.—Pitch is stated by the author to be dissolved readily and completely by benzol prepared from coal-tar, whereas benzine, also known as ligroine or petroleum spirit, hardly dissolves the substance alluded to at all.

No. 8, 1871.

The only original paper in this number is the pharmacognostic essay on the—

Gum and Gum-Resin producing Plants which are met with in the Steppe district of Central Asia.—Dr. R. Palm.

No. 9, 1871.

Does not contain any original papers relating to chemistry.

No. 10, 1871.

The only original paper relating to chemistry is on the—

Freezing of Aqueous Solutions of Salts.—Dr. G. C. Wittstein.—The author placed (at St. Petersburg) the undermentioned solutions of salts, prepared in larger quantity and kept in stoppered bottles, in a store-room, the temperature of which was for several consecutive weeks below 0° , but never below -6° . The saline solutions which remained unfrozen were—Ammonium chloride (1-5), antimoniate of potassa (1 of the granular salt to 240), hydrate of baryta (1-19), barium chloride (1-9), calcium chloride (1-9), acetate of baryta (1-9), neutral acetate of lead (1-9), basic acetate of lead (1-9), ferrocyanide of potassium (1-9), ferricyanide of potassium (1-9), iodide of potassium (1-9), sulphocyanide of potassium (1-9), hydro-fluosilicic acid (1-16), carbonate of ammonia (1-9), carbonate of potassa (1-9), carbonate of soda (1 cryst. salt to 6), molybdate of ammonia (1-19), oxalate of ammonia (1-29), bichloride of mercury (1-19), nitrate of baryta (1-19), nitrate of lead (1-9), proto-nitrate of mercury (1-19), proto-sulphate of iron (1-4), sulphate of potassa (1-14), sulphate of magnesia (1-9), tartaric acid (1-4), protochloride of tin (1-9). The following solutions were frozen:—Oxalic acid (1-9), phosphate of soda (1-14), nitrate of silver (1-49), and sulphate of lime (1-490). The figures between parentheses indicate the proportion of the salts to that of water.

No. 11, 1871.

The only original paper relating to chemistry is an essay on—**Aluminium Chlorhydrate (so-called Chloralum), and on some other Alumina Compounds.**—Dr. E. Thorey.

Journal für Praktische Chemie, No. 10, 1871.

This number contains the following original papers and memoirs:—

Synthesis of Normal Propyllic Alcohol, Ethyl-Alcohol being taken as the starting-point.—A. Rossi.—The author first prepared cyanethyl, converted that into propionate of lime, and, by distilling that along with formate of lime, obtained the aldehyde of the propionic acid, which, being treated with sodium amalgam, became converted into propylic alcohol. That alcohol is a colourless, mobile fluid, soluble in water in all proportions, and boiling at 96° ; sp. gr. at 0° , 0.8205; formula, C_3H_7O . The author further describes some of the haloïd combinations of propyl obtained from the alcohol alluded to.

Mineralogico-Chemical Researches.—Von Kobell.—This paper treats on the following subjects:—Monzonite, a new mineral species.—The mineral here alluded to was found on the Monzoni mountains, in the Fassathal (Tyrol). The colour of the mineral is light greyish-green; it is hard and compact, rather readily fusible before the blowpipe, sp. gr. 3.0, and soluble in concentrated phosphoric acid. The composition of the mineral, in 100 parts, was found to be the follow-

ing:—Silica, 52.60; alumina, 17.10; protoxide of iron, 9.0; lime, 9.65; magnesia, 2.10; soda, 6.60; potassa, 1.90; water, 1.50;—total, 100.49. Marcellin consists, in 100 parts, of—Oxide of manganese, 66.68; oxide of iron, 10.04; protoxide of manganese, 8.79; protoxide of iron, 1.30; lime, 1.14; magnesia, 0.26; silica, 10.21. Behaviour of sulphuret of bismuth with iodide of potassium before the blowpipe (bismuthite from St. José, in Brazil).—When iodide of potassium is mixed with sulphuret of bismuth, and ignited upon charcoal before the blowpipe, the coal is coated with a beautiful deep red-coloured film of iodide of bismuth. Pure metallic bismuth does not, under the same conditions, give this reaction; but, when the metal is rubbed along with some sulphur, and then ignited, as just alluded to, the same phenomenon is observed, but gradually the red colour fades and the film becomes yellow. Bismuthite, of a peculiar grass-green colour, and structure akin to green pyromorphite, was found by the author among some Brazilian minerals. On mixing this mineral (carbonate of bismuth) with iodide of potassium and sulphur, and igniting it before the blowpipe, it gave also the reaction above alluded to, which is highly characteristic for bismuth.

Observations made while Analysing various samples of Commercial Tin.—Dr. T. Scheerer.—The author chiefly points out the variable composition of some of the sulphurets of tin, and communicates an analysis of meta-sulphuret of tin dried over sulphuric acid, and found to consist, in 100 parts, of—Tin, 57.14; sulphur, 29.36; water, 16.50. Formula, $SnS_2 + 2H_2O$. The same substance, dried at 140° —Tin, 59.0; sulphur, 32.0; water, 9.0. Formula, $SnS_2 + H_2O$.

New Method of Separating Magnesia from Potassa and Soda.—Dr. T. Scheerer.—Reserved for full translation.

Rosolic Acid.—H. Fresenius.—The contents of this paper, although valuable, are not suited for any useful abstraction.

NOTES AND QUERIES.

Diamond Dust.—(Reply to Josiah Lowe).—By digesting the dust along with hydrofluoric acid, as commercially sold, in either leaden or platinum vessels, you will be able to dissolve the glass, leaving the diamond-dust unattacked.

Skein Silk.—C. R. Stevens will find that silicate of soda will decompose muriate of tin without the aid of heat. It may be used very much diluted, and does not injure cotton or wool. He will find, by experiment, the strength most available for silk.—T. F.

Schio-Liao.—(Reply to E. J. L.).—Among the constituents of blood is found a substance which, from its tough fibrous nature, has received the name of fibrine. This is eliminated from fresh and warm blood by beating it with a bundle made of thin willow or birch twigs. The fibrine adheres to the twigs, and blood so treated remains fluid, instead of, as is otherwise the case, coagulating. We think that at many of the larger slaughter-houses you can buy defibrinated blood.

Manufacture of Alum.—(Reply to "A.").—You would do well to consult Payen's "Chimie Industrielle," also Wagner's "Jahresberichte über die Fortschritte der Technologie," and Elsner's "Chemisch-Technischen Mittheilungen," all of which you will inspect at the Library of the Commissioners of Patents, where you will also find several other periodicals and books, published recently in various countries, treating on technology and chemistry applied to manufacturing industry.

TO CORRESPONDENTS.

* * The Students' Number of the *CHEMICAL NEWS* will be published on Friday, September 8th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our Office for publication in that number, will confer a favour by sending it with the least possible delay.

Chemists.—The subject is treated very fully in an English edition of Wagner's "Chemical Technology." The work is now in the press and will be published by Messrs. J. and A. Churchill.

G. J. Warner.—The volume containing index to Gmelin's "Handbook" has not yet been published.

A. Keilfuhrer and Co.—One of the best works on the subject is "Traité des Arts Céramiques," par A. Brongniart; Paris: Béchot. Mr. Murray has published a work by J. Marryat on "A History of Pottery and Porcelain, Mediæval and Modern."

T. Limmers, jun.—(1). You may be able to obtain the journal containing the paper through Nutt and Co., Foreign Booksellers, Strand. (2). Consult article on the subject in Ure's "Dictionary of Arts and Sciences."

W. Foster.—Received with thanks.

A. Glendinning.—Thanks for the communication; it shall receive attention.

C. J. S.—See reply to E. J. L. in our "Notes and Queries" column.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

VOL. XXIV. No. 615.

(STUDENTS' NUMBER.)

SCHOOLS OF CHEMISTRY.

EXAMINING BOARDS.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this Examination is £2.

The Examination will be held on Monday, January 8th, 1872, and includes the following subjects:—

NATURAL PHILOSOPHY.*

Mechanics—

Composition and Resolution of Statical Forces.

Simple Machines (*Mechanical Powers*):—Ratio of the Power to the weight in each.

Centre of Gravity.

General Laws of Motion, with the chief Experiments by which they may be illustrated.

Law of the Motion of Falling Bodies.

Hydrostatics, Hydraulics, and Pneumatics—

Pressure of Liquids and Gases, its equal diffusion, and variation with the depth.

Specific Gravity, and modes of determining it.

The Barometer, the Syphon, the Common Pump and Forcing-Pump, and the Air-Pump.

Acoustics—

Nature of Sound.

Mode and Rate of Propagation of Sound.

Musical Tones.

Optics—

Laws of Reflection and Refraction.

Formation of Images by Simple Lenses.

CHEMISTRY.

Heat—its sources. Expansion. Thermometers—relations between different Scales in common use. Difference between Temperature and Quantity of Heat. Specific and Latent Heat. Calorimeters. Liquefaction. Ebullition. Evaporation. Conduction. Convection. Radiation.

Chemistry of the Non-Metallic Elements; including their compounds as enumerated below—their chief physical and chemical characters—their preparation—and their characteristic tests.

Oxygen, Hydrogen, Carbon, Nitrogen. Chlorine, Bromine, Iodine, Fluorine. Sulphur, Phosphorus, Silicon.

Combining Proportions by weight and by volume. General Nature of Acids, Bases, and Salts. Symbols and Nomenclature.

The Atmosphere—its constitution; effects of Animal and Vegetable Life upon its composition.

Combustion. Structure and Properties of Flame, Nature and Composition of ordinary Fuel.

Water. Chemical peculiarities of Natural Waters, such as rain-water, river-water, spring-water, sea-water.

Carbonic Acid. Carbonic Oxide. Oxides and Acids of Nitrogen. Ammonia. Olefiant Gas, Marsh Gas, Sulphurous and Sulphuric Acids, Sulphuretted Hydrogen.

Hydrochloric Acid. Phosphoric Acid and Phosphoretted Hydrogen. Silica.

BACHELOR OF SCIENCE (B.Sc.)

This degree is conferred on candidates who pass a satisfactory examination in Mathematics, Mechanical and Natural Philosophy, Botany, and Vegetable Physiology, Zoology, and Chemistry.

FIRST B.Sc. EXAMINATION.

No candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The examination will commence on Monday, July 17th, 1872. It is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

The First Examination includes the following subjects:—

NATURAL PHILOSOPHY.

Heat—

Sources of Heat; conduction—convection.

Effects of Heat; expansion generally—of water—of gases and vapours; liquefaction; vaporisation; latent heat; expansive form of steam; dew-point; gases and vapours compared.

Specific Heat.

Thermometers; Pyrometers.

Heat in the Radiant state.

Electricity—

Sources of Electricity.

Static Electricity; dual character—insulation—induction—specific inductive capacity—equivalent antithetic states—disruptive discharge—convection; Electroscopes—Leyden jar, &c.

Dynamic Electricity; Conduction—the electric current—derived currents—induction of currents; Voltaic Pile and other voltaic arrangements.

Thermo-Electricity; Electro-Thermometer.

Magnetism—

Magnets, the Earth, &c.; Induction—communication—retention—Magnetic relations of iron, steel, &c.

Electro-Magnetism—as in the spark—in conducting media—in soft iron; Magneto-Electricity; principle of Electro-magnetic and Magneto-Electric machines.

Terrestrial Magnetism.

INORGANIC CHEMISTRY.

Matter; simple and compound.

Elementary bodies classed. Metallic and Non-Metallic bodies.

Chemical Combination and Mechanical Mixture. Solution.

Outlines of Crystallography. Isomorphism. Dimorphism. Allotropic conditions of matter. Chemical Affinity, Laws of Combination by weight and by volume, as deduced from the history of the individual elements. Equivalent Numbers. Equivalent Volumes. Symbolical Notation, including questions on the Unitary System. Formulæ. Nomenclature.

Chemical actions produced under the influence of Heat. Nature of Combustion. Structure and Properties of Flame. Principles of Illumination. Chemical action of Light. Photography.

Oxygen. Ozone.

Hydrogen. Water.

Nitrogen. Chemical constitution of the Atmosphere. Diffusion of Gases. The Oxides of Nitrogen; Nitric Acid. Ammonia.

Chlorine, Bromine, and Iodine. Their compounds with Oxygen and Hydrogen. Theory of Bleaching.

Fluorine and Hydrofluoric Acid.

* The Questions in Natural Philosophy will be of a strictly elementary character.

Sulphur. Sulphurous Acid. Manufacture and Chemical applications of Sulphuric Acid. Other Oxygen compounds of Sulphur. Sulphuretted Hydrogen.

Phosphorus. Oxygen and Hydrogen compounds of Phosphorus. Theory of Acids. Monobasic, Dibasic, and Tribasic Acids.

Carbon. Carbonic Oxide and Carbonic Acid. The principal Hydrogen compounds of Carbon. Manufacture of Coal Gas.

Silicon and Boron. Their compounds with the elements previously enumerated.

Metals. Characters of Metals as a class. Metallurgical Processes. Alloys. Classification of the Metals.

Potassium. Nitre. Gunpowder. Theory of the action of Gunpowder.

Sodium. Manufacture of Carbonate of Soda.

Barium. Strontium. Calcium. Mortars. Cements.

Magnesium. Aluminum. Glass. Porcelain.

Manganese. Iron. Composition and properties of Cast-Iron, Wrought-Iron, and Steel. Chromium.

Cobalt. Nickel. Zinc. Cadmium.

Lead. Manufacture of White-Lead.

Copper. Mercury. Bismuth. Tin. Arsenic. Antimony.

Silver. Gold. Platinum.

Principal compounds of the Metals with the Non-Metallic Elements. Theory of Salts.

Principles of Mineral Analysis.

Principles of Electro-Chemistry.

For the First Examination, a knowledge of Inorganic Chemistry only is necessary.

EXAMINATION FOR HONOURS.

Candidates for Honours in Chemistry are examined in any of the following subjects, at the option of the Examiners:—

Elementary Substances and their combinations.

Electro-Chemistry.

Radiant Chemical Action.

In the Examination for Honours, the Candidate, being not more than twenty-two years of age, who most distinguishes himself in Chemistry and Natural Philosophy, will receive an Exhibition of Forty pounds per annum for the next two years.

SECOND B.Sc. EXAMINATION.

This Examination commences on Monday, October 23rd. Candidates for this Examination who have not previously taken the degree of B.A. are required either to have passed the First B.Sc. Examination at least one Academic year previously, or to have passed the First M.B. Examination, in this University.

The Fee for this Examination is £5.

This Examination embraces Organic Chemistry, including the following subjects:—

Ultimate analysis of Organic bodies. Calculation of Empirical Formulæ. Methods of controlling Empirical Formulæ. Determination of the Equivalents of organic acids and bases; examination of products of Decomposition: determination of the Vapour-density of volatile bodies.

Law of Substitution. Compound Radicals. Homologous Series.

The Chemical History of the Cyanogen group. Cyanogen. Hydrocyanic Acid. Cyanic Acid and Urea. Fulminates. Cyanuric Acid. Sulphocyanic Acid. Chlorides of Cyanogen. Uric Acid.

Amylaceous and Saccharine substances. Fermentation. Alcohol, Wine, Beer, Bread, &c.

Homologues of Alcohol. Ethers, simple and mixed. Oxidation of Alcohol. Aldehyde and Acetic Acid, and their homologues. Anhydrides, simple and mixed. Compound Ethers.

Diatomic Alcohols and their Acids. Glycol and Oxalic Acid and their homologues.

Triatomic Alcohols. Glycerine. Fatty and Oily bodies. Saponification.

Vegetable Acids;—the principal.

Ammonia and its Derivatives. Ammonium and Ammoniacal Salts. Amides and Amines; their Classification. The chief Natural Organic Bases.

Colouring Matters. Indigo and its derivatives. Principles of Dyeing.

The chief constituents of the Vegetable organism. Cellulose, Vegetable Fibrin. Albumen, Casein, Glutin, &c.

The chief constituents of the Animal organism. Animal Fibrin, Albumen, Casein, Gelatin. Blood, Milk, Bile, Urine, &c.

Decay, Putrefaction. Destructive Distillation.

The Chemical Principles of the process of Nutrition and of Respiration in Plants and Animals.

EXAMINATION FOR HONOURS.

The Candidate, not more than twenty-three years of age, who, in the Examination for Honours, most distinguishes himself in Chemistry, will receive Fifty pounds per annum for the next two years, with the title of University Scholar.

DOCTOR OF SCIENCE (D.Sc.).

This Examination is held within the first twenty-one days of June, and occupies four days.

No Candidate is admitted to the Examination for the Degree of D.Sc. until after the expiration of two Academic years from the time of his obtaining the Degree of B.Sc. in this University.

Candidates for the Degree of D.Sc. in any year, must give notice of their intention to the Registrar, and pay to him a Fee of Ten pounds, on or before the 1st of April.

Chemical Candidates can be examined either in Inorganic or Organic Chemistry; but no Candidate will be approved by the Examiners unless he has shown a thorough practical knowledge* of the *Principal Subject*, and a general acquaintance with the *Subsidiary Subject*, or *Subjects*, specified as belonging to the Branch so selected.

Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or, Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or, Chemical Technology, in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

EXAMINATIONS IN CONNECTION WITH THE DEPARTMENT OF SCIENCE AND ART, SOUTH KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom.

This sum is administered by the Science and Art Department.

The object of the grant is to promote instruction in Science, especially among the industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools and classes.

The following are among the Sciences towards instruction in which aid is given:—Acoustics, Light, Heat, Magnetism, and Electricity, Inorganic Chemistry, Organic Chemistry, Geology, Mineralogy, Mining, Metallurgy.

The assistance granted by the Science and Art Department is in the form of—1. Public Examinations, in which Queen's Medals and Queen's Prizes are awarded, held at all places complying with certain conditions. 2. Payments on results to teachers. 3. Scholarships and Exhibitions. 4. Building Grants. 5. Grants towards the purchase of apparatus, &c.

* It must be understood that the candidate for the Degree of D.Sc. is expected to be so fully conversant with the principal subject he may select, as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied.

CHEMICAL LECTURES AND LABORATORY INSTRUCTION.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Dean.—Professor A. W. Williamson, Ph.D., F.R.S.

Vice-Dean.—Professor G. Fuller, C.E.

The Session begins on Tuesday, the 3rd of October, and ends on Friday, the 21st of June.

It is divided into three terms, as follows: Michaelmas term, from October 3rd until December 20th; Lent term, from January 4th, 1872, till March 16th; Summer term, for Lectures, from March 18th till June 6th, all inclusive.

Chemistry.—Professor Williamson, Ph.D., F.R.S.

A. GENERAL COURSE.

Lectures daily, except Saturday, from 11 to 12 a.m.

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m.

Fee for the Whole Course of Lectures, £6 6s.; for a Half Course, £3 3s.; Perpetual, £9 9s.; for the Organic Course alone, £2 2s.

Fee for the Exercise-Class—For the Course, £2 2s.; for the Half Course, £1 1s.

The Instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of Exercises and personal instruction on the subject of the Lectures by Tutors, under the direction of the Professor.

The First Half of the Course to Christmas includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Second Half of the Course, extending from January to March, includes the following subjects:—

I. Preparation and properties of the chief metals, including their characteristic reactions and most important salts. Detection of Metallic Poisons. Quantitative Estimation of Metals. Principles of Classification. Monatomic Diatomic Metals, &c.

A weekly *viva voce* examination is held during the First Half Course and the commencement of the Second Half Course.

II. Organic Chemistry.

This commences in the second week in February, and occupies Five Lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers, colouring matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of fermentation, &c.

Teachers of Chemistry are trained in the theory and practice of their profession. A two years' Course is absolutely requisite for this purpose; but Students will with advantage devote a longer period to it.

The first year is occupied with attendance on the Courses of Chemistry and of Analytical Chemistry. In the second year the Student again attends the Course of Chemistry, and is entrusted with teaching work in conjunction with the Tutors of the Class. At the same time time he continues to work in the Laboratory at analysis and original research.

In order to qualify themselves for rising to the higher ranks of the Profession, gentlemen remain for a further period, in which case they may obtain remunerative work in teaching through the recommendation of the Professor.

B. ANALYTICAL AND PRACTICAL CHEMISTRY.

I. BIRKBECK LABORATORY.

The instruction in the Laboratory is intended for beginners as well as for more advanced students. It includes practice in the construction and use of apparatus for preparing the common gases, acids, bases, salts, &c.,

study of the qualitative methods of detecting and separating mineral or organic bodies from one another; also quantitative analyses in the wet way, organic analyses, vapour-densities, &c.; instruction in gas analysis.

More advanced students are instructed in the methods of original research, especially in organic chemistry.

When accompanied or preceded by attendance on the Lectures on Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture &c. Instruction is given in the principles and processes of Gas Analysis.

The Laboratory and Offices are fitted up completely with the most improved apparatus and utensils for experimental research, both for beginners, and for advanced Students. They are open daily, from 9 a.m. to 4 p.m., from the 4th of October until the end of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials. A deduction of about 40 per cent is made for Students who can attend only three fixed days per week.

A Gold Medal and Certificates of Honour are competed for by students entered for the Session.

II. SUMMER COURSES.

I. Elementary Course.

About Forty Lessons, of one hour each, on Tuesday, Wednesday, Thursday, and Friday, from 11 to 12, commencing in the first week of May. Students are taught the construction and use of apparatus for the preparation of the most important gases, acids, &c. The characteristic tests for the presence of the common acids and bases, including the chief metallic and other poisons. Also the processes for separating these bodies from one another.

Solutions are frequently given in the class for investigation.

The first six weeks of the Course are occupied by the study of the chief non-metallic elements, and their simple compounds. Metallic salts, &c., are subsequently studied.

Fee, including cost of materials and apparatus, for the Course, £4 4s.; perpetual, £7 7s.

II. Senior Course.

This Course consists of Twenty Lessons, of two hours each, on Mondays and Saturdays, from 10 to 12, commencing in the first week in May. The first half of the Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerine, alkaloids, &c.

The second half of the Course includes tests for mineral poison in organic mixtures; also tests for organic bodies, such as uric acid, albumen, sugar, alkaloids, &c., when mixed with other organic compounds, as in urine, blood, &c., or in food.

Volumetric methods of the quantitative analysis of sugar and urea are practised.

Fee, including cost of materials and apparatus, for the Course, £4 4s.; perpetual, £7 7s.

C. SUMMER MATRICULATION COURSE.

Professor Williamson, F.R.S., assisted by Mr. F. S. Barff, M.A., F.C.S.

This Course includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of Oral Lessons. The Practical Lessons include the preparation of the common gases and acids, &c., and the study of their characteristic properties in relation to the elementary laws of combination.

The other lessons are chiefly devoted to those parts of the subject which require fuller oral explanation than is given in the practical lessons. They include numerous

exercises and questions, to which answers in writing are given by the Students. These Lessons will begin on Wednesday, April 5th, at 11 a.m.

The class will meet on Tuesdays, Wednesdays, Thursdays, and Fridays, from 11 to 12; and some other meetings will be announced when the Class has assembled.

Fee for the class, £4 4s., including cost of materials and apparatus.

EVENING CLASSES.

The Session is divided into three Terms, each of ten complete weeks, exclusive of vacations—

I. The Michaelmas Term, beginning on Monday, the 9th of October, and ending on Thursday, December 14th.

II. The Lent Term, beginning on Monday, the 8th of January, and ending on Thursday, March 14th.

III. The Summer Term, beginning on Monday, the 18th of March, and ending on Thursday, June 6th; the Easter Vacation extending from the 28th of March to the 8th of April, both days inclusive.

The object of these classes is to extend the benefits of the College Tuition especially to gentlemen engaged elsewhere during the day, and to provide instruction in subjects not taught in the ordinary College Classes.

The Beadles have orders to admit gentlemen to any of the Classes, with the permission of the Professor or Teacher, as occasional visitors.

The Library is open for the convenience of the Students between 6.30 and 8.30 on the evenings when the Classes meet, except when it is wanted for other purposes.

Elementary Chemistry—Theoretical and Practical.

Professor Williamson, F.R.S., and Mr. Jones. Monday, from 6.30 to 8.30.

A Course of Twenty Lessons, of two hours each, in the Michaelmas and Lent Terms.

The elements of Chemistry are explained to the Class, and the experiments illustrating the subject are performed by the Students.

The subject will be the common Non-Metallic Elements and the common Metals, their compounds and chief Properties, and the best method of distinguishing and separating them.

All the experiments and analyses are repeated by each Student, or by not more than two Students jointly.

Fee, including the cost of materials, &c., £4 4s. for the whole course, or £2 2s. per Term.

ROYAL SCHOOL OF MINES AND COLLEGE OF CHEMISTRY.

Professor of Chemistry.—Dr. E. Frankland, F.R.S.

The instruction in Chemical Science embraces:—

1. A course of Lectures on Experimental Chemistry, with special reference to the applications of Chemistry in the Arts and Manufactures.

2. A systematic Laboratory Course for the Practice of Chemical Analysis.

Chemical Lectures.—The Course consists of Forty Lectures on Mineral Chemistry and Thirty Lectures on Organic Chemistry.

The Lectures are delivered at the Royal College of Chemistry, Oxford Street.

Chemical Laboratory.—The general Laboratory for instruction in chemical manipulation in qualitative and quantitative analysis, and in the method of performing chemical researches, is under the direction of Dr. Frankland, and will be opened on Monday, the 2nd of October, 1871. The Royal College of Chemistry being the property of the Government, its Laboratories are used for the instruction of the pupils of the Royal School of Mines.

There are three terms in the collegiate year, of three months each, commencing in the first week of October, January, and April respectively. The Laboratory hours are from 10 a.m. to 5 p.m., with the exception of Saturdays, when the Laboratory closes at 2 o'clock.

Each Laboratory Student works independently, there being no classes. All operations are superintended by

the Professor and his assistants. A table with drawers, cupboards, and shelves, is appropriated to every pupil. The institution supplies gas, fuel, and reagents. The larger and more expensive instruments of the Laboratory, such as air-pumps, thermometers, barometers, condensers, &c., may be used by the students, who are held responsible for their safety. The students have to provide themselves only with the apparatus specified in the Laboratory regulations. More advanced students engaged in private researches have to supply themselves with such materials as are not included amongst the ordinary reagents of the Laboratory.

Professor of Metallurgy.—Dr. Percy, F.R.S.

The course of instruction in Metallurgy consists of Lectures and Laboratory Practice.

The object of the Lectures is the communication of such instruction as the student may be able to apply to the greatest practical advantage, when he may be subsequently engaged in conducting any metallurgical process.

Metallurgical Laboratory.—This Laboratory is conducted by Mr. R. Smith, under the direction of Dr. Percy, and is devoted to practical instruction in Metallurgy. It will be opened on the 2nd of October, 1871. The nature of this instruction will be adapted to the special requirements of the Students. It comprises:—Assaying in all its branches, especially of the more important metals, such as iron, copper, lead, tin, alloys of silver and gold, &c., and the examination of ores and metallurgical products.

The ability of the student to make trustworthy assays is in every case thoroughly tested; and no certificate of competency is given to a student who has not furnished satisfactory proof that he is able to obtain accurate results.

There are three terms in the collegiate year of three months each. The Laboratory hours are from 10 to 4 during November, December, January, and February; and from 10 to 5 during the other months, with the exception of Saturdays, when the Laboratory is closed.

The charge for instruction in the Metallurgical Laboratory is £15 for three months; £12 for two months; and £7 for one month.

Lectures to Working Men.—Short Courses of Lectures at suitable periods of the year are given in the evening to working men. These courses are systematic, and arranged so as to illustrate, within a period of two years, the principal subjects taught at the Institution. Those for the ensuing Session include Chemistry, Metallurgy, Physics, Applied Mechanics.

KING'S COLLEGE.

Professor of Chemistry and Practical Chemistry.—C. L. Bloxam, F.C.S.

Demonstrator.—W. N. Hartley.

Assistant do.—J. M. Thompson.

The session commences on the 2nd of October, 1871. Students of the first and second years are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a view of the forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic Elements and their principal compounds are described.

The metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts, and the processes of the different Manufactures of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *viva voce* and by written papers, are held at intervals during the course at the usual Lecture hour.

Third Year.—Students who have completed six Terms in this Department are admitted to a course of Practical Chemistry, consisting of Twelve Demonstrations in each term; and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this department may be admitted to this Class at any period of his study, on payment of an extra fee.

Analytical and Experimental Chemistry.—Besides the Course of Chemical Lectures and the Summer Class of Practical Chemistry, provision is made for those Students who wish to become more minutely acquainted with the practical details of the Science. By means of this Class each Student is enabled to familiarise himself with the methods of analysis and research. After passing through a preliminary course of analytical operations, each Student devotes himself to such portions of the science as are most interesting to himself, or most likely to be practically useful to him. The Daniel Scholarship of £20, tenable for two years, is given every alternate year for original research in the Laboratory.

The Fees for admission to the Laboratory Class, exclusive of materials, are, for one month, £4 4s.; for three months, £10 10s.; for six months, £18 18s., &c.

EVENING CLASSES.

Classes for Evening Instruction are held at King's College from October to March, and during April, May, and June.

The Classes include one for the Elements of Chemistry and one for Practical Chemistry.

The fee for the former is £1 11s. 6d.; for the latter, £2 2s. The classes meet twice a week.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

17, BLOOMSBURY SQUARE, W.C.

School of Pharmacy. The Session (1871-72) will commence on Monday, October 2nd, and extended to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY DR. REDWOOD.

These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock.

Part 1.—Physics in relation to Chemistry and Pharmacy.

„ 2.—Chemistry of Inorganic Bodies.

„ 3.—Chemistry of Organic Bodies.

Also Lectures on Botany and Materia Medica, by Professor Bentley. The first and second parts of this course, extending over the winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 a.m. The third part of the course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park, at 8 a.m.

Fees.—For registered apprentices and associates of the Society, for either of the above courses, £1 1s.; for either part separately, 10s. 6d. For those not connected with the Society, £2 2s. for either of the above courses; £1 1s. for either part separately. Students have free admission to the Library and Museum.

Laboratory.—The suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on Monday, the 2nd of October, under the direction of Professor Atfield, Ph.D. Fee for the entire session of ten months, Twenty-five Guineas. The Laboratories are open from 9.30 a.m. till 5 p.m. Students can enter at any period during the session.

Two Scholarships (the Jacob Bell Memorial Scholarship) of Thirty Pounds a year each, are open to competition annually in July.

The Board of Examiners meet monthly, and are required by the Pharmacy Act to examine "all candidates who may present themselves for examination in their knowledge of the Latin Language, in Botany, in Materia Medica, in Pharmaceutical and General Chemistry, and to grant Certificates of Competency."

CITY OF LONDON COLLEGE, LEADENHALL STREET, E.C.

The Annual Courses consist of three terms, each averaging ten experimental lectures: fee, 5s. per term. Subjects:—Junior Class, Chemistry—first year, Non-Metals; second year, Metals and (time permitting) Elements of Organic Chemistry. Senior class, 7 to 8 p.m., Practical Analysis.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION.

EVENING CLASSES.

Inorganic Chemistry—Mr. G. Chaloner. Tuesday, 8 to 9.
Practical Chemistry and Analysis—From 8 to 10, Saturday evenings.

ISLINGTON SCHOOL OF SCIENCE,
WINDSOR STREET, ESSEX ROAD, N.

A Course of Thirty Lessons on Inorganic Chemistry, by Mr. J. Howard, on Fridays at 8.30. Fee, 5s.

Practical Chemistry and Qualitative Analysis.—Fridays, at 6.30.

Electricity and Magnetism.—Wednesdays, at 8.

NEW KENNINGTON INSTITUTE.

Lectures and Practical Classes in Chemistry, Pharmacy, Practical Chemistry, Botany, Materia Medica, Latin, Physics, and all subjects connected with the Pharmaceutical Examinations, under the direction of Dr. Muter. Popular Chemical Evening Classes for Commercial Analysis.

POLYTECHNIC INSTITUTION.

Course of Thirty Lessons in Inorganic Chemistry, under the superintendence of Professor Pepper. Tuesday, 8.30 to 10 p.m.

ROYAL VETERINARY COLLEGE, CAMDEN TOWN.

Chemical Professor.—Mr. R. V. Tuson.

LECTURES AT LONDON MEDICAL SCHOOLS.

ST. BARTHOLOMEW'S HOSPITAL & MEDICAL COLLEGE.

WINTER SESSION.

Lecturer.—Dr. W. J. Russell. Monday, Wednesday, and Friday, at 10 a.m. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. W. J. Russell. One course, £2 2s.

CHARING CROSS HOSPITAL AND COLLEGE

WINTER SESSION.

Lecturer.—Mr. C. W. Heaton, F.C.S. Monday, Thursday, and Friday, at 11. One session, £5 5s.

The Laboratory is open daily.

SUMMER SESSION.

Practical Chemistry.—Mr. Heaton, F.C.S. Monday and Friday. One session, £2 2s.

ST. GEORGE'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. H. M. Noad, F.R.S. Tuesday, Thursday, and Saturday, at 11.30. One course, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Dr. Noad, F.R.S. Monday, Wednesday, Thursday, Friday, at 10. One course, including the use of apparatus and materials, £4 4s.

GUY'S HOSPITAL.

WINTER SESSION.

Lecturers.—Dr. Debus, F.R.S., and Dr. Stevenson. Tuesday, Thursday, and Saturday, at 11. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Dr. Debus, F.R.S. Monday, Wednesday, and Friday, from 10 to 1. One course, £4 4s. Practical Instruction is also given in the laboratory by Drs. Debus and Stevenson during the Winter Session.

The Course of Lectures on Experimental Philosophy (Heat, Electricity, Magnetism, and Electro-Magnetism) is given on Wednesdays at 12 noon by Dr. Stevenson.

LONDON HOSPITAL.

Lecturers on Chemistry.—Henry Letheby, M.B., and C. Meymott Tidy, M.B. Monday, Wednesday, and Friday, at 10.30 a.m.

Practical Chemistry.—Dr. Letheby, M.B. Monday, Tuesday, and Saturday, at 9 a.m.

ST. MARY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. C. R. A. Wright, F.C.S. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. C. R. A. Wright, F.C.S. Tuesday and Thursday, at 11.30 a.m.; and Saturday, at 9 a.m. One session, £3 3s.

MIDDLESEX HOSPITAL.

WINTER SESSION.

Lecturer.—Mr. Heisch. Monday, Wednesday, Friday, and Saturday, at 11. One session, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Mr. Heisch. Monday, Wednesday, and Friday, at 11. One session, £3 3s.

ST. THOMAS'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. J. Bernays. Wednesday, Thursday, and Friday, at 9. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. J. Bernays. Tuesday and Thursday, 10 to 12; Friday, 11; Saturday, 10 to 1. One course, £3 3s.

WESTMINSTER HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 3 p.m.; Friday, at 3.30 p.m. One course, £5.

SUMMER SESSION.

Practical Chemistry.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 10 a.m. One course, £2.

PRIVATE TEACHERS OF CHEMISTRY IN LONDON.

Mr. J. C. Braithwaite, 54, Kentish Town Road, N.W.—Chemistry and Toxicology, Monday and Thursday; Latin, Tuesday and Friday; Botany and Materia Medica, Wednesday and Saturday. All the classes commence at 8 p.m. Laboratory and Botanic Garden open daily, except Saturdays.

Mr. Henry Matthews, F.C.S.—Laboratory, 60, Gower Street, Bedford Square. Instruction in all branches of Practical Chemistry, particularly in its application to Medicine, Agriculture, and Commerce. Laboratory open daily, except Saturday, from 10 to 5; on Saturday, from 10 to 1.

Dr. John Muter, M.A.—Laboratory, 289, Kennington Road. Prepares for examinations of Pharmaceutical Society.

Mr. John Newlands, F.C.S.—Laboratory, 13, Knowle Road, Brixton, S.W. Gives practical instruction in Analysis, and prepares gentlemen for various public examinations.

Mr. A. Vacher, 20, Great Marlborough Street, Regent Street.

UNIVERSITY OF OXFORD.

Professor of Chemistry.—Sir B. C. Brodie, Bart., M.A., F.R.S.

Demonstrator.—E. Madan, M.A.

A commodious Laboratory is attached to the New Museum.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other Colleges, by competitive examination in Natural Science.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A.

MICHAELMAS TERM.

Practical Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m.

LENT TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

EASTER TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

The Chemical Laboratory of the University is open daily, from 10 a.m. till 6 p.m.; so that students can work there at such times as may be convenient to them: and the Professor will attend to give instruction at the times above specified.

PROVINCIAL SCHOOLS.

BIRMINGHAM.—MIDLAND INSTITUTE.

Lecturer on Chemistry.—Mr. C. J. Woodward, B.Sc. Tuesday and Thursday, at 8 p.m.

Practical Chemistry.—Mr. C. J. Woodward, B.Sc. Saturday, 3 to 6, and 6.30 to 9.30 p.m.

BIRMINGHAM.—QUEEN'S COLLEGE.

WINTER SESSION.

Professor of Chemistry.—Alfred Hill, M.D., Borough Analyst. Tuesday, Thursday, and Friday, at 12.

SUMMER SESSION.

Practical Chemistry.—Professor A. Anderson. Thursday and Friday, at 2 p.m.

BRISTOL.—BRISTOL MEDICAL SCHOOL.

WINTER SESSION.

Lecturer.—Mr. Thomas Coomber, F.C.S. Monday, Tuesday, Wednesday, and Thursday, at 8.15. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—M. T. Coomber, F.C.S. Daily except Saturday, at 8 a.m. One course, £3 3s.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—A. H. Church, M.A. Oxon.

Assistant.—E. Kinch.

The Autumn Session commenced on the 15th of August: it divides on the 6th of October, and terminates about the 21st of December.

The chemical instruction comprises Three Courses of Lectures and Laboratory Practice:—

- (1). 32 Lectures on Inorganic Chemistry.
- (2). 32 Lectures on Organic Chemistry.
- (3). 24 Lectures on Agricultural Chemistry.
- (4). 32 Lessons on Chemical Manipulation.
- (5). 32 Lessons on Qualitative Analysis.
- (6). 32 (or more) Lessons on Quantitative Analysis.

Catechetical Lectures are also given, while analyses of manures, oil-cakes, minerals, soils, waters, &c., are daily performed in the College Laboratories, and Chemical-Agricultural researches undertaken by the more advanced

Students, under the immediate direction of Professor Church.

The text-books used are Church's "Laboratory Guide," Roscoe's "Chemistry," and Church and Dyer's edition of "How Crops Grow."

LIVERPOOL ROYAL INFIRMARY SCHOOL OF MEDICINE.

Lecturer on Chemistry and Toxicology.—Dr. J. Campbell Brown.

1. Course of 100 Lectures. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.
2. Practical Organic Chemistry for Senior Students. £3 3s.
3. Practical Chemistry. Summer Class; Fifty Lessons. £3 3s.
4. Toxicology. Twelve Lectures.
5. Technical Students are admitted on five days of the week into the Private Laboratory, which is open from 10 to 4.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 AND 9, HACKIN'S HEY, LIVERPOOL.

Conducted by Mr. A. Norman Tate.

Pupils may attend at any time between the hours of 9.30 a.m., and 5 p.m. (Saturdays, 9.30 a.m. and 4 p.m.) and may work every day, or any numbers of days, or portion of a day in the week, and for any period most convenient to themselves.

The Laboratory is also open two evenings per week for practical work.

Lectures one evening each week.

A separate working bench is provided for each Student, and he is also supplied with all ordinary chemicals, gas, fuel, and the more substantial portions of Laboratory apparatus, but must provide himself with test-tubes, beakers, and other apparatus of a fragile nature.

In addition to the ordinary chemical studies, the course of instruction will, as far as possible, comprise all such studies as may be required for the successful prosecution of the particular branch or branches of Applied Chemistry in which the pupil is to engage; as, for example, in the case of one intended for manufacturing pursuits, he would study architectural and mechanical drawing, so far as is required for the preparation of plans, &c., of chemical apparatus and manufactories, the nature and use of building materials, and the scientific principles and practical rules involved in building and constructive operations, and other scientific and practical information required in the arrangement, construction, and management of chemical manufactories, and the application of Chemistry to industrial pursuits.

COLLEGE OF CHEMISTRY, LIVERPOOL.

Founder.—Dr. Muspratt, M.D., &c.

Principal.—Mr. Martin Murphy, F.C.S., Professor of Chemistry.

The Course of Instruction given in the College of Chemistry comprises the teaching of Chemistry as a science, and the general application of chemical knowledge; also the teaching of the principles of those branches of physics which are allied with chemistry, such as light, heat, electricity, &c.

Particular attention is devoted to instruction in the practice of systematic analytical operations, whereby students will be enabled to determine accurately the general and proximate constituents of substances, and so arrive at a knowledge of their nature and properties.

Instruction in the application of chemical data to medicine and agriculture, and to the chemical and metallurgical operations, comprising Technology, will be given, to qualify students for these avocations.

The students will invariably be controlled and directed in their study and work by the Principal and competent assistants. Ample laboratory accommodation is provided

for students, and such general appliances as will facilitate their progress in acquiring a knowledge of the specialities taught in the college.

The student's laboratories are open throughout the year. Hours of attendance—From 10 a.m. to 5 p.m. daily.

Fees—10 guineas per quarter of 3 months, or 35 guineas per annum, payable in advance. Students provide all their own apparatus and books.

Medical and Pharmaceutical students are admitted for 1 hour per day. Fee for 3 months, £2 2s.

A Course of Lectures will be delivered to the students during the winter months. Evening Classes.

Certificates of attendance recognised by the University and Apothecaries' Hall of London, and Apothecaries' Hall of Ireland.

LEEDS SCHOOL OF MEDICINE.

WINTER SESSION.

Lecturer.—Mr. J. Chapman Wilson, F.C.S.

Daily, except Saturday, at 11 a.m. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Mr. Wilson, F.C.S.

Tuesdays and Thursdays, 11 to 12.30. One course, £2 2s.

LEEDS MECHANICS' INSTITUTION AND LITERARY SOCIETY'S LABORATORY.

SESSION 1871—72.

Chemical Classes for Instruction in Elementary, Practical, and Analytical Chemistry.

Teacher.—Mr. George Ward, F.C.S.

HIGH HARROGATE COLLEGE, YORKSHIRE.

Professor of Chemistry.—Mr. W. G. Mason, F.C.S., Certificated Science Teacher.

MANCHESTER GRAMMAR SCHOOL.

CHEMICAL DEPARTMENT.

Professor.—W. Marshall Watts, D.Sc. Lond.

Instruction is given in Inorganic Chemistry, Organic Chemistry, Metallurgy, and Analytical Chemistry. A lecture-room and second laboratory, affording accommodation for seventy-two students, have just been completed.

Michaelmas Term commences on Tuesday, September 19th.

MANCHESTER ROYAL SCHOOL OF MEDICINE.

Lecturer on Chemistry.—Mr. Daniel Stone.

The usual course for the Medical Boards.

A Laboratory is connected with the school.

OWEN'S COLLEGE, MANCHESTER.

(IN CONNECTION WITH THE UNIVERSITY OF LONDON).

Chemistry.—Professor H. E. Roscoe, B.A., Ph.D., F.R.S., F.C.S.

Junior Class.—Wednesday and Saturday, from 9.15 to 10.15 a.m.

Subject: Inorganic Chemistry, comprising the laws of chemical combination, and a description of the properties and mode of preparation of the non-metallic elementary bodies and their most important compounds.

Senior Class.—Tuesday and Thursday, from 9.15 to 10.15 a.m.

Subjects: Inorganic and Organic Chemistry, including the properties of the metals and their compounds, and the composition and relations of the best defined groups of organic bodies, and the laws regulating their formation.

Students are expected to answer the written exercises and attend the *viva voce* examinations given in these classes.

Fee—For each class, £3 3s. For both classes, £5 5s.

A *Recapitulatory Lecture*, without additional Fee, will be given on Friday at 9.15 a.m., which members of both classes will be required to attend.

Extra Class.—Wednesday, from 4 to 5 p.m.

Subject: Technological Chemistry.

The Chemical Principles involved in the most important Chemical Manufactures will be chiefly considered in this course.

Students attending this class must be acquainted with the principles of Chemical Science. Fee, £2 2s.

Analytical and Practical Chemistry.

LABORATORY COURSE.

Professor.—Henry E. Roscoe, B.A., Ph.D., F.R.S.

Senior Assistant.—Mr. C. Schorlemmer, F.R.S.

The aim of this course is to make the student practically acquainted with Chemical Science, to enable him to conduct analysis and original research, and to fit him for applying the science to the higher branches of Art, Manufactures, and Agriculture. To accomplish this, an attendance of not less than four days per week during three whole sessions is as a rule necessary. It is very advisable that each Laboratory Student should attend or should have attended the course of Lectures on Theoretical Chemistry.

The College Laboratory will be open for students daily from 10.30 a.m. until 5 p.m., except Saturdays, when it will be closed at 1.30. The Laboratory is closed from 1.15 until 2, for dinner.

The Laboratory is fitted with every convenience for the prosecution of practical chemistry, all branches of qualitative and quantitative analysis, and original research.

Each student is provided with a separate working table, set of tests, fuel, water, and gas, free of expense; but he is required to find his own apparatus, a few of the more expensive reagents, and the chemicals required for his experiments. Other apparatus or instruments of a more expensive description may be obtained on loan from the Laboratory Steward, subject to regulations to be prescribed by the Professor.

Fees for the Session.—Students working six days per week, £21; ditto, four days, £17 17s.; ditto, three days, £13 13s.; ditto, two days, £9 9s.; ditto, one day, £5 5s.; Students entering the Laboratory Class at or after Christmas, for not less than two days per week, will be charged two-thirds of the fees for the whole session.

Special Fees for Shorter Periods.—For six months, six days per week, £17 17s.; five months, ditto, £15 15s.; four months, ditto, £13 13s.; three months, ditto, £10 10s.; two months, ditto, £7 7s.; one month, ditto, £4 4s.

Lectures on the methods of Qualitative and Quantitative Analysis, intended to supplement the instruction in Practical Chemistry, will be given by Mr. Schorlemmer, on Mondays, from 4 to 5 p.m.

First year's Laboratory Students are recommended to attend and answer the written exercises and the *viva voce* questions given in this class. Fee, £1 11s. 6d.

Chemical Calculations.—In this class, instruction and special practice is given, by Mr. Schorlemmer, on Wednesday, from 4 to 5 p.m., in the methods of Chemical Calculations, serving as supplementary to the Lecture and Laboratory Courses. Fee, £1 1s.

The Lectures on Chemistry in Owen's College are recognised by the University of London for its Medical Degrees, by the Royal College of Surgeons, and by the Apothecaries' Hall.

EVENING CLASSES.

Chemistry.

Professor H. E. Roscoe, B.A., Ph.D., F.R.S.

Lecture Class.—(First Course—The Non-Metallic Elements).—Monday, from 8.35 to 9.35 p.m.

Lecture Class.—(Second Course—The Metals). Friday, from 8.35 to 9.35 p.m.

Lecture Class.—(Third Course—Organic Chemistry).—Mr. C. Schorlemmer, F.R.S. Thursday from 8.35 to 9.35 p.m.

Laboratory Courses of Practical Chemistry.

Professor Roscoe, F.R.S., and Mr. Schorlemmer, F.R.S.

Junior and Senior Divisions.—Monday, From 6 to 8.30 p.m.

Pharmaceutical Course.—Monday and Wednesday.

COLLEGE OF PHYSICAL SCIENCE, NEWCASTLE.

(IN CONNECTION WITH THE UNIVERSITY OF DURHAM).

Professor of Chemistry.—A. Freire-Marreco, M.A.

First Course.—Michaelmas Term: General Principles of Chemistry; History of the Non-metallic Elements.

Second Course.—Epiphany Term: History of the Metals and their more important compounds; Principles of Qualitative Analysis, Monday, Tuesday, Wednesday, and Thursday, at 9 a.m.; Examinations, Friday at 9 a.m.

Third Course.—Easter Term: Elements of Organic Chemistry, Monday and Wednesday, at 9 a.m.; Examinations, Friday at 9 a.m.

Mineralogical Chemistry, Tuesday and Thursday, at 9 a.m.; Examinations, Saturday at 9 a.m. Fee, five guineas; single Courses, two guineas each.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it closes at 1 p.m.

Laboratory Fees.—Students working six days per week, five guineas per term. Students working alternate days, three guineas per term. Students working one day per week, one guinea per term.

SHEFFIELD.

SCHOOL OF CHEMISTRY,

1, SURREY STREET, SHEFFIELD.

Mr. A. H. Allen, F.C.S., delivers a Course of Twenty-four Lectures on Applied Chemistry, in connection with the Science and Art Department.

Day and Evening Classes for Analytical Chemistry.

SHEFFIELD SCHOOL OF MEDICINE.

During the Winter Session, Mr. A. H. Allen, F.C.S. will deliver a Course of Forty-five Lectures on Chemistry.

The Practical Chemistry Class, will meet three times a week during the Summer Session.

Mr. W. Baker, F.C.S., lectures on Chemistry at the Sheffield Collegiate School. Laboratory for Instruction in Theoretical and Practical Chemistry, 46, High Street, Sheffield.

SCOTLAND.

UNIVERSITY OF EDINBURGH.

Professor of Chemistry.—Dr. A. Crum Brown, F.R.S.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS, EDINBURGH.

Lecturer on Chemistry.—Dr. Stevenson Macadam, F.R.S.E.

The Courses of Instruction in Chemistry include its applications to Medicine, Agriculture, and the Industrial Arts; and they qualify for the University of Edinburgh and other Universities, the Royal Colleges of Physicians and Surgeons, the Navy, Army, and Indian Medical Service, and the other Medical and Public Boards.

The Lectures on Chemistry are delivered daily during the five months of the Winter Session. The Lectures form a complete Course; the New Nomenclature and Notation are employed throughout, and special Lectures in Technological Chemistry are given. Tutorial Class Examinations are held during the Session, and Excursions are arranged for visiting the principal Chemical Manufactories.

The Instructions in Analytical Chemistry are conducted in the Laboratories at Surgeons' Hall, which are now open daily, under the personal superintendence of Dr. Macadam, for the instruction of gentlemen in Chemical Analysis, and the prosecution of researches in Manipulative Chemistry.

The Prelections in Practical Chemistry are also conducted in the Laboratories at Surgeons' Hall. The subjects

selected for Examination are those with which Medical Students are specially called upon to exhibit a practical acquaintance.

Fees.—Lecture, £3 5s. (University Graduation, £4 4s.) Practical Chemistry (University, &c.), £3 3s.; Analytical Chemistry, £2 per month, £5 for three months, or £10 for six months.

UNIVERSITY OF GLASGOW.

Professor of Chemistry and Practical Chemistry.—Dr. Thomas Anderson, F.R.S.E.

ANDERSONIAN UNIVERSITY, GLASGOW.

Professor of Scientific Chemistry.—Dr. T. E. Thorpe.

GLASGOW MECHANICS' INSTITUTION.

Professor of Chemistry and Practical Chemistry.—Dr. R. Carter Moffat.

GLASGOW VETERINARY COLLEGE.

Professor of Chemistry.—Dr. R. Carter Moffat.

IRELAND.

DUBLIN.—TRINITY COLLEGE.

Professor of Chemistry.—Dr. Apjohn, F.C.S.

ROYAL COLLEGE OF SURGEONS, DUBLIN.

Professor of Chemistry.—Dr. Barker.

QUEEN'S COLLEGE, BELFAST.

Professor of Chemistry.—Dr. Andrews, F.R.S., &c.

QUEEN'S COLLEGE, CORK.

Professor of Chemistry.—Dr. Blyth.

QUEEN'S COLLEGE, GALWAY.

Professor of Chemistry.—Dr. T. H. Rowney.

A Laboratory for Practical Instruction is attached to all the Queens' Colleges. The usual Practical Course for the Medical Boards is given in the summer.

ROYAL COLLEGE OF SCIENCE FOR IRELAND, STEPHEN'S GREEN, DUBLIN.

This college supplies, as far as practicable, a complete course of Instruction in Science, applicable to the Industrial Arts. The subjects of Instruction are:—Pure and Applied Mathematics, Descriptive Geometry, and Mechanical Drawing, Mechanism, Theoretical and Applied Chemistry, Chemical Analysis, Physics, Botany, Zoology, Geology, and Palæontology, Mineralogy, Mining, Machinery, Surveying, and Agriculture.

Professor of Theoretical Chemistry.—W. K. Sullivan, Ph.D., V.P.R.I.

Professor of Analytical and Applied Chemistry.—R. Galloway, F.C.S.

Assistant Chemist.—W. Plunkett, F.C.S.

A course of Lectures on Inorganic and Organic Chemistry is delivered by Dr. Sullivan three times a week during the session. Fee for the entire course, £2.

A course of Lectures on Technological Chemistry is delivered by Mr. Galloway twice a week during the session. Fee for the course, £2.

The chemical and Metallurgical Laboratories, under the direction of Mr. Galloway, are open every week day during the session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical research. Each student is taught, not in class, but separately and independently; and he is supplied with a separate working table, with reagents, fuel, water, gas, and the larger and more expensive apparatus. Fee, for the session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships, of the value of £50 each, yearly, with free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with free Education, including Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the annual May Examinations of the Science and Art Department.

A Diploma of Associate of the College is granted at the end of the three years' Course.

The Session commences on Monday, October 2nd.

NOTE ON REGIANIC ACID.*

By Dr. T. L. PHIPSON, F.C.S.

REGIANIC acid is one of several new substances which I have obtained during the last few years from the fruit of *Juglans regia*, and also from another species of walnut. To these substances allusion has already been made at a previous meeting of the British Association, and in the *Comptes Rendus* of the Paris Academy. The green husk of the walnut yields to benzol a yellowish substance crystallising in very elongated octahedra or feather-like groups of crystals. This substance, which I call *regianine*, is easily decomposed, and, when treated with alkalis or ammonia, gives a splendid purple-red solution, whence acids precipitate a brown floccuous substance. The latter, re-dissolved in a weak solution of soda, re-precipitated with hydrochloric acid, after the addition of which the solution is boiled and washed with boiling water, gives a jet black amorphous substance, which is pure *regianic acid*, yielding to analysis the composition $C_6H_6O_7$, and forming a brown lead salt, $PbO, C_6H_6O_7$, also a jet black silver salt, very similar in appearance to the acid itself, and a lime salt of a beautiful pink colour, the precipitation of which is hastened by boiling with a little ammonia. Regianic acid is insoluble in water, but dissolves in alkaline solutions with a fine red-purple tint. These coloured solutions have no peculiar action upon the spectrum. It appears to be derived from *regianine* by oxidation, for when the latter is introduced with a little soda into a given volume of air, the whole of the oxygen is absorbed. Regianine is soluble in water, alcohol, and benzol; but its solution in benzol is the only one that can be kept for any length of time. The alcoholic solution is rapidly decomposed by exposure to the air and regianic acid, more or less pure, deposited.

LABORATORY NOTES.

ON THE DISTINCTION BETWEEN A PHOSPHATE AND AN ARSENIATE.

It is well known that the difference in colour between silver phosphate and silver arseniate furnishes the most simple means of distinguishing between the two classes of salts. Presence of free nitric acid or ammonia interfering with the reaction, it is necessary to apply the test to a neutral solution, in which case many other salts may be precipitated. If the phosphate or arseniate be first separated as the ammonia magnesium salt, it is usual to dissolve this precipitate in nitric or acetic acid before adding silver nitrate. This is quite unnecessary, the characteristic yellow phosphate or brown arseniate being immediately produced on addition of silver nitrate to the crystalline precipitate. This modification renders the test more delicate as the reaction takes place in a neutral liquid. A few streaks on a test-tube show the reaction very distinctly, hardly changing colour if due to

* Abstract of a Paper read before the British Association, Edinburgh Meeting, Section B.

phosphate, but turning quite brown if caused by arseniate, in each case becoming soluble in ammonia. On this account the ammonio-magnesium salt must be washed free from ammonia, which would either prevent the reaction or lead to confusion by precipitating brown silver oxide. Acetic acid dissolves both phosphate and arseniate of silver, the former far more readily than the latter. If, therefore, acetic acid be gradually added to a mixed precipitate of silver phosphate and arseniate, the phosphate dissolves first, and the brown colour of the arseniate becomes more apparent. If, after addition of a moderate quantity of acetic acid, the liquid be filtered, the dissolved phosphate may often be detected by cautious neutralisation with ammonia, when the yellow silver phosphate is thrown down, but this reaction is uncertain, as both phosphate and arseniate of silver are soluble in ammonium acetate, the phosphate more readily than the arseniate.

ALFRED H. ALLEN, F.C.S.

Sheffield, August 26, 1871.

MISCELLANEOUS.

New Appointment.—Mr. James Kilroe, ex-scholar of the Royal College of Science, Dublin, has been appointed Science Teacher in the Trade School at Saltaire, Leeds.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Moniteur Scientifique, Nos. 331 and 332 (double number), August 1 and 15, 1871.

This number contains the following original papers and memoirs bearing on chemistry and collateral sciences:—

Anthracen and its Derivatives.—Dr. E. Kopp.—We regret that it is impossible to quote here more than the headings of the various sections of this very complete and exhaustive monograph on this subject:—The anthracens of commerce—(a) crude anthracen of German origin, (b) crude anthracen of English, (c) of French manufacture; preparation of chemically pure anthracen; properties of semi-purified anthracen; properties of absolutely pure anthracen; formation and synthesis of anthracen—(1) by means of toluol or toluen, (2) by the action of heat alone upon toluol, (3) by the reaction of ethylen and styrolen upon benzine; hydrogenated derivatives from anthracen; action of chlorine upon anthracen. This essay is to be continued.

Best means of Artificial Illumination of Workshops and Factories.—A. Joulet.—This essay, illustrated by a woodcut, treats at length on Rouille's autogen gas apparatus, already alluded to by us before (see *CHEMICAL NEWS*, vol. xxiv., p. 74).

Short Notes on the Maritime Exhibition held at Naples last year.—A. Joulet.—This paper contains, among other interesting matter, some particulars on a new instrument invented by M. Esposito, and termed a *nausismograph*—viz., a contrivance which may be briefly described as an automatic log-book. This apparatus is highly eulogised by naval authorities of high standing—English, American, Russian, French, and others—and especially, also, by the eminent mathematician, the Rev. Father A. Secchi, S.J. Very properly the author of this paper here observes, "Parlez moi de sciences mathématiques pour produire l'accord entre des hommes venus de points opposés."

Bayerisches Industrie und Gewerbe Blatt, June, 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

Milk and Lactometers.—P. Neumann.—A lecture on this subject in its most exhaustive sense, treating, not simply on milk as usually understood, but on that fluid as secreted by mammalia in general, and also quoting a series of analyses of milk, the modes of testing milk, preserving it, and statistics relating to the number of

cows found in various countries, per mille of the population thereof, and a detailed description of the various lactoscopes, lactometers, and other similar instruments.

Utility and Value of Carbonic and Lactic Acids in Beer.—A. Vogel.—The contents of this paper really bear upon the question, What effect have newly-built cellars upon Lager beer which is kept in casks? From a comparative experiment made by the author, it appears that, when fresh lime can absorb the carbonic acid contained in beer, the effect thereof is that the liquor becomes rapidly stale. As regards the lactic acid, a permanent constituent of good beer, it is due to the malt, and is of importance for keeping proteine compounds in solution in beer.

American Journal of Pharmacy, August, 1871.

In addition to several original papers and memoirs more particularly bearing upon pharmacy, this number contains the following original papers relating to chemistry:—

Bromide of Cerium.—C. Bullock.—The author prepares this salt (which, it appears, is used as medicine in the United States) by first taking oxalate of cerium, which, having been calcined in a porcelain capsule, the resulting sesquioxide was dissolved in hydrochloric acid (with copious evolution of chlorine). To the chloride of cerium thus obtained, carbonate of soda was added, yielding white carbonate of cerium insoluble in an excess of the alkaline carbonate. The carbonate of cerium was dissolved in hydrobromic acid, requiring nearly twice the weight of the sesquioxide in bromine as hydrobromic acid for saturation. The solution of bromide of cerium decomposes while evaporating, even at a low temperature, disengaging acid fumes. When evaporated to dryness, and pulverised, the salt has a light chocolate colour; the taste is somewhat sweet and very styptic. The salt is very deliquescent, and dissolves in alcohol of 95 per cent. The dry salt leaves an insoluble sediment in water, which sediment, of a light grey colour, was found to be protoxide of cerium.

Note on Chloral Hydrate.—Ch. A. Böhme.—The author relates at length an occurrence which appears to lead to the conclusion that chloral hydrate may be spontaneously decomposed when kept in sealed bottles, two of these, each containing 1 lb. of the substance alluded to, having been obtained from a leading drug-house at New York. One of the bottles was opened at once, and nothing special noted in its contents; the other bottle was placed in a store-room, and on being after some time opened, a dense cloud of fumes was observed to issue from its mouth. These fumes had the characteristic odour of chloral hydrate, but were more stifling, reddened blue litmus-paper, and, on further testing, were found to consist partly of hydrochloric acid. The lumps of the hydrate near the top of the bottle had crumbled to a crystalline powder freely soluble in water, somewhat in chloroform, but insoluble in sulphide of carbon and oil of turpentine. The author's opinion is that the sample alluded to might have been pure hydrate of chloral at first, and been decomposed by standing.

Action of Chlorides on Calomel.—J. Cummings.—According to Mialhe, calomel is in part converted into bichloride of mercury (corrosive sublimate) and metallic mercury, by chloride of ammonium and the chlorides of sodium and potassium. Dr. Gardner denies this statement. The author communicates a series of experiments made for the purpose of correctly ascertaining the real truth about these different assertions with the result that, in the case of the ammonium-chloride, there is some minute quantity of bichloride of mercury formed at 110° F., when the ammonium-chloride is, along with water, in contact with the calomel. With the chloride of sodium, the calomel is not so readily converted into bichloride, requiring thereto a higher temperature; but the addition of some drops of hydrochloric acid hastens the reaction. Calomel, digested alone with the acid just named for twelve hours at a temperature of 120° F., undergoes the same change, but is not affected at a lower temperature.

Analysis of a Silver Ore from Austin, Nevada.—J. L. Beeler.—In 100 parts, this ore was found to consist of—AgCl, 0.94; AgSi 47.60; SbS₃, 11.31; PbS, 11.75; Cu₂S, 1.19; FeS₂, 3.23; SiO₂, 23.63 loss, 0.35—total, 100.0.

Shoe-Blacking without Acid.—Dr. Artus.—From 3 to 4 lbs. of lamp-black and $\frac{1}{2}$ lb. of bone-black are well mixed with 5 lbs. of glycerine and treacle. Meanwhile, 2½ ozs. of gutta percha are cautiously fused in a copper or iron saucpan, and 10 ozs. of olive oil added, with continual stirring, and afterwards 1 oz. of stearine. The warm mass is added to the former mixture, and then a solution of 5 ozs. of gum senegal in 1½ lbs. of water, and 1 drachm each of oil of rosemary and lavender may be added. For use, the blacking is diluted with 3 to 4 parts of water. This blacking keeps the leather soft, and renders it more durable.

La Revue des Scientifique de la France et de l'Etranger, August 5, 1871.

This number does not contain any original papers relating to chemistry and thereto allied sciences, but we call attention to the lectures on the—

Influence of Heat Externally Applied to Animals.—Dr. C. Bernard.—Interesting in a physiological experimental view.

Climate of the Alsace.—Ch. Grad.—A valuable contribution to physical geography and meteorology.

August 12, 1871.

Contains no original papers relating to chemistry or collateral sciences.

Royal School of Mines.—Director, Sir Roderick IMPEY MURCHISON, Bart., K.C.B., F.R.S., &c.
During the Twenty-first Session, 1871-72, which will commence on the 2nd of October, the following COURSES of LECTURES and PRACTICAL DEMONSTRATIONS will be given:—

1. Chemistry. By E. Frankland, Ph.D., F.R.S.
2. Metallurgy. By John Percy, M.D., F.R.S.
3. Natural History. By T. H. Huxley, LL.D., F.R.S.
4. Mineralogy. } By Warington W. Smyth, M.A., F.R.S.
5. Mining. }
6. Geology. By A. C. Ramsay, LL.D., F.R.S.
7. Applied Mechanics. By T. M. Goodeve, M.A.
8. Physics. By Frederic Guthrie, F.R.S.
9. Mechanical Drawing. By the Rev. J. Haythorne Edgar, M.A.

The Fee for Students desirous of becoming Associates is £30 in one sum, on entrance, or two annual payments of £20, exclusive of the Laboratory fees.

Pupils are received in the Royal College of Chemistry (the Laboratory of the School), under the direction of Dr. Frankland, and in the Metallurgical Laboratory, under the direction of Dr. Percy.

Tickets to separate Courses of Lectures are issued at £3 and £4 each.

Officers in the Queen's Service, Her Majesty's Consuls, Acting Mining Agents and Managers may obtain Tickets at reduced prices.

Science Teachers are also admitted to the Lectures at reduced fees. His Royal Highness the Prince of Wales grants Two Scholarships, and several others have also been established by Government.

For a Prospectus and information, apply to the Registrar, Royal School of Mines, Jermyn Street, London, S.W.

TRENHAM REEKS, Registrar.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

South London School of Chemistry and Pharmacy, directed by Dr. JOHN MUTER, M.A., F.C.S., &c.

Specially rapid preparation for Examination in CHEMISTRY, BOTANY, MATERIA MEDICA, PHARMACY, FORENSIC MEDICINE, and CLASSICS.

The New Laboratory has been fitted up on the most modern principles, and a complete Dispensing Department and Botanical Garden added to the School.

A few Articled Pupils received (when a vacancy occurs) for Instruction in Commercial Analysis and Microscopy.

* * * Analyses and Research conducted for the Profession with rapidity, accuracy, and at special discount.

289, KENNINGTON ROAD, LONDON, S.E.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c.

Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latio, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871-1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

BERNERS COLLEGE of CHEMISTRY.

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily. Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience. Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Veterinary College, Great College Street, Camden Town, London.

The Lectures will commence at the above Institution on Tuesday, October 3rd.

The Introductory Address will be delivered by Deputy Professor Pritchard, at 12 o'clock.

Anatomy, Physiology, and Pathology of the Horse—Professor Spooner.

Anatomy, Physiology, and Pathology of other Domesticated Animals—Professor Simonds.

Descriptive Anatomy, with Physiology—Deputy Professor Pritchard. Chemistry, Materia Medica, and Toxicology—Professor Tuson.

Anatomical Demonstrations—Assistant Professor Axe.

Infirmary Practice and Clinical Instruction daily—Professors Spooner, Simonds, and Pritchard.

Perpetual Fee to all the Lectures, with Infirmary Practice and Anatomical Demonstrations daily, 25 guineas.

It is desirable that intending Pupils should present themselves at the Royal Veterinary College for Matriculation at 10 o'clock a.m. precisely on Tuesday, the 26th of September next. Matriculation fee 1 guinea.

A Prospectus will be forwarded on application. CHARLES SPOONER, Principal.

August 25th, 1871.

St. Mary's Hospital Medical School.—Open SCHOLARSHIP AND EXHIBITION IN NATURAL SCIENCE.

A SCHOLARSHIP of the value of £40, tenable for three years, and an EXHIBITION of the value of £20, for one year, will be awarded by open competitive Examination in Natural Science, at St. Mary's Medical School, on September 26th and following days.

Any person will be eligible as a candidate who has passed an Examination qualifying him to register as a Medical Student, provided he has not previously completed a full year of medical study at a recognised Hospital.

Candidates are requested to call personally upon the Dean at the School, on Monday, Sept. 25th, between the hours of 3 and 5 p.m., and to bring with them a certificate of having passed the required preliminary Examination.

Further information as to the subjects of Examination, and the conditions under which the Scholarship and Exhibition will be held, may be obtained from Dr. Cheadle, the Dean, or from Mr. Knott, the Registrar, at the Hospital.

W. B. CHEADLE, M.D., Dean of the School.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

Liverpool Royal Infirmary School of Medicine.

Lecturer on Chemistry and Toxicology—Dr. J. CAMPBELL BROWN.

1. Course of 100 Lectures. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.
2. Practical Organic Chemistry for Senior Students. £3 3s.
3. Practical Chemistry. Summer Class. Fifty lessons. £3 3s.
4. Toxicology. Twelve Lectures.
5. Technical Students are admitted on five days of the week into the Private Laboratory, which is open from 10 to 4 for consultation and analyses.

OWEN'S COLLEGE, MANCHESTER,

IN CONNEXION WITH THE UNIVERSITY OF LONDON.

Principal—J. G. GREENWOOD, B.A.

PROFESSORS AND TEACHERS:—

J. HOLME NICHOLSON, Registrar.

TECHNICAL EDUCATION.

SCIENCE AND ART DEPARTMENT.

Royal College of Science for Ireland,

STEPHEN'S GREEN, DUBLIN.

SESSION—1871-72.

THIS College supplies, as far as practicable, a complete Course of Instruction in Science applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

The Course of Instruction is recognised by the Secretary of State for India as Qualifying for Appointments in the Engineering Department.

There are Four Royal Scholarships, of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in the College. There are also Nine Exhibitions attached to the College, of the yearly value of £50 each, with Free Education and Laboratory Instruction, tenable for three years. Three become vacant each year. These are awarded at the Annual May Examinations of the Science and Art Department.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory.

The Laboratory Fee is £12 for the full Course of nine months, or £2 per month.

SUBJECTS OF INSTRUCTION.

Applied Mathematics, Mechanism and Machinery, Descriptive Geometry, Geometrical, Mechanical, and Engineering Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology and Palaeontology, Mining, Surveying, Agriculture.

The Laboratory is open for Instruction in Practical Chemistry, Metallurgy, and Assaying, from ten to four o'clock every week-day during the Session, except Saturdays and Holidays.

The Session commences on MONDAY, OCTOBER 2.

Programmes may be obtained on application to the Secretary, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

University of Aberdeen.—Chancellor, His Grace the Duke of Richmond. Vice-Chancellor and Principal, the Very Rev. P. C. Campbell, D.D. Lord Rector, M. E. Grant Duff, M.A., M.P.

FACULTY OF MEDICINE—SESSION 1871-72.

WINTER SESSION, Commencing on Wednesday, November 1.
Anatomy—Professor Struthers, M.D. 11 a.m. £3 3s.
Practical Anatomy and Demonstrations—Professor Struthers and Demonstrator. 9 to 4, and 9 a.m. £2 2s.
Chemistry—Professor Brazier. 3 p.m. £3 3s.
Institutes of Medicine—Professor Ogilvie, M.D. 4 p.m. £3 3s.
Surgery—Professor Pirrie, C.M., F.R.S.E. 10 a.m. £3 3s.
Practice of Medicine—Professor Macrobain, M.D. 3 p.m. £3 3s.
Midwifery and Diseases of Women and Children—Professor Inglis, M.D. 2 p.m. £3 3s.
Zoology, with Comparative Anatomy—Professor Nicol, F.G.S. 2 p.m. £3 3s.
Medical Logic and Medical Jurisprudence—Professor Ogston M.D. 9 a.m. £3 3s.

SUMMER SESSION, commencing on the First Monday of May.
Botany—Professor Dickie, M.D. 9 a.m. £3 3s.
Materia Medica (100 Lectures)—Professor Harvey, M.D. 3 and 4 p.m. £3 3s.
Practical Anatomy and Demonstrations—Professor Struthers and the Demonstrator. 9 to 4, and 2 p.m. £2 2s.
Practical Chemistry—Professor Brazier. 10 a.m. £3 3s.
Zoology, with Comparative Anatomy—Professor Nicol. 11 a.m. £3 3s.

The Anatomical Course in Summer includes instruction in General Anatomy and in the use of the Microscope; and Instruction in Osteology for Beginners.

Matriculation Fee (including all dues) for the Winter and Summer Sessions, £1. For the Summer Session alone, 10s.

Royal Infirmary: Daily at Noon. Physicians—Drs. Harvey, Smith, and Beveridge. Surgeons—Drs. Pirrie, Kerr, and Fiddes. Junior Surgeon—Dr. A. Ogston. Ophthalmic Surgeon—Dr. A. D. Davidson. Dental Surgeon—Mr. Williamson. Pathologist—Dr. Rodger. Perpetual Fee to Hospital Practice, £6; or, first year, £3 10s; second year, £3.

Clinical Medicine—Drs. Harvey, Smith, and Beveridge. £3 3s.
Clinical Surgery—Drs. Pirrie, Kerr, and Fiddes. £3 3s.
Pathological Anatomy—Dr. Rodger. £2 2s.
A Three Months' Course of Practical Ophthalmology is given in Summer by Dr. A. D. Davidson, commencing early in May.
General Dispensary, and Lying-in and Vaccine Institution: Daily, Eye Institution: Daily.

Practical Midwifery, under the superintendence of Dr. Inglis.
Royal Lunatic Asylum: Physician—Dr. Jameson. Clinical Instruction is given for Three Months in the Year.

The Regulations relative to the Registration of Students of Medicine, and the granting of Degrees in Medicine and Surgery, may be had of Dr. Macrobain, Dean of the Faculty of Medicine.

Full information regarding the Classes and Degree in the Faculties of Arts, Law, and Divinity, and in regard to Bursaries and Scholarships, will be found in the UNIVERSITY CALENDAR, published by Messrs. Wylie and Son, Union Street, Aberdeen—By Post, 2s. 2d.

Royal 8vo., with 7 Lithographs and 50 Woodcuts, price 6s. cloth.

Microscopical Manipulation; being the subject matter of a Course of Lectures delivered before the Quekett Microscopical Club, January–April, 1869. By W. T. SUFFOLK, F.R.M.S.

London: Henry Gillman, Boy Court, Ludgate Hill.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND Co., 20, King William Street, Strand.

THE CHEMICAL NEWS.

VOL. XXIV. No. 616.

OBSERVATIONS ON CLEAN AND UNCLEAN SURFACES IN VOLTAIC ACTION.*

By THOMAS BLOXAM.

Lecturer on Chemistry, Cheltenham College.

IF a piece of amalgamated zinc is made to touch a piece of platinum in the presence of acidulated water, the well-known extraction of hydrogen bubbles takes place from the latter metal. Whilst trying a series of such experiments, and also some of a similar nature, I observed an unequal evolution of bubbles from some parts of the platinum plate, and accordingly submitted the matter to enquiry.

The first series of experiments had for their object to ascertain the amount of gas evolved in a given time from a zinc and platinum plate in contact.

Expt. 1. A tube graduated to 1 cubic inch was filled with water acidulated with $\frac{1}{10}$ th of strong sulphuric acid; a strip of platinum as obtained from the apparatus makers was cut 7-in. long, $\frac{1}{4}$ -in. wide; introduced into the tube which was then inverted upon a small plate of amalgamated zinc also standing in the same acid and water. The time at starting and at the termination was accurately recorded, as also the temperature and pressure throughout all the experiments. Time resulting from a mean of many experiments was 22 minutes.

Expt. 2. The strip cleaned by heating it in oil of vitriol, and thoroughly rinsing in distilled water, gave as a mean result. Time 14 minutes.

Expt. 3. The strip merely passed through the finger several times. Time 28 minutes.

It will be seen from these results that the platinum as it leaves the instrument makers is absolutely, so to speak, chemically dirty; but the mere contact with the hand is sufficient to materially modify the action.

The strip cleaned by oil of vitriol was dipped for a moment into solution of common salt, and again tried when the time required for collecting the cubic inch of hydrogen was nearly doubled.

The strip having been made dirty by touching, was ignited in the flame of a good Bunsen lamp for one minute, and then arranged in the cubic inch tube. The time required was fifteen minutes, thus showing that it had been in great measure cleaned, though hardly so satisfactorily as in the heating with oil of vitriol.

Expt. 4. was devoted to the action of copper negative plates in similar strips to the platinum; the mean results in these cases were that copper cleaned with nitric acid and washed in distilled water gave the cubic inch of hydrogen in twenty-one minutes. The strip passed through the fingers as in the platinum experiments. Time required 28 $\frac{1}{2}$ minutes.

A strip of copper oxidised by heating in air furnished the hydrogen in ten minutes.

It would appear from these results, that copper behaves in a similar way as to cleanness of surface as platinum, and that the oxidised surface tends rather to facilitate the liberation of the hydrogen—perhaps from mechanical action, like platinised silver.

Expt. 5. Platinised silver, as obtained from the makers, arranged in the same way as the foregoing experiments, furnished the 1 cubic inch hydrogen in 2 $\frac{1}{2}$ minutes. A strip cleaned with oil of vitriol as usual, time 2 $\frac{1}{2}$ minutes. A strip made dirty by the fingers, time 3 minutes.

Hence it appears that the mechanical action of the platinum surface is of great importance, as has been well known, and that as received from the makers it is very considerably cleaner than the new platinum, because, probably, of its method of preparation.

It was also found that, comparing smooth with mechanically roughened surfaces of platinum, the latter furnished the hydrogen in two-thirds of the time taken by the former.

Expt. 6. A cell of Seebeck's battery was examined by the galvanometer, using in every case a regular strength of acid, the same wires and all conditions the same, when the following results were obtained:—

The negative plate not chemically cleaned, deflection = 52°.

Negative plate chemically cleaned, 57°.

Negative plate made dirty by fingers, 48°.

The platinum taken off the surface gave deflection 50°.

Here it appears, then, that the cleaning of the surface of the platinised silver materially diminishes the resistance due to the counter-current and polarisation.

The last series of experiments were directed to ascertain the influence of chemically clean surfaces upon electrolysis.

A voltameter, the electrodes of which were in their ordinary state, was attached to two cells of Bunsen's battery, and the mixed gases collected with all precaution. The time taken for 1 cubic inch was 2 minutes as a mean of many experiments.

The electrodes were then cleaned with hot oil of vitriol, the Bunsens freshly charged, and the 1 cubic inch of gases was furnished in 1 $\frac{1}{2}$ minutes; thus showing that electrolysis is materially affected by the state of cleanness of the electrodes at the time.

ON THE DISSOCIATION OF MOLECULES BY HEAT.*

By C. R. C. TICHBORNE, F.C.S., M.R.I.A., &c.

DISSOCIATION has been, and is now, applied to phenomena somewhat distinct from ordinary decompositions.

Decomposition specifies that some molecular change has been consummated, whilst dissociation is used to convey a passive but present phenomenon. If this latter phenomenon is carried far enough, it must ultimately result in a rupture, and thus the phenomena of decomposition and dissociation are so intimately connected that they can hardly be investigated alone. We may familiarly illustrate the dissociation influence of heat to the stretching of a piece of india-rubber, in which the dissociative force of heat is here represented by the fingers; the particles (emblematic of molecules) of india-rubber are here held asunder by the force—but when removed the rubber regains its primitive construction. This stretch may be carried on to a wonderful extent, but there is a limit, for at last a point is attained at which the rubber breaks. Compound molecules exist as solids, liquids, and gases, providing that the temperature necessary to convert them into these physical modifications is not above the temperature at which their components are dissociated. Now we can easily conceive that a substance, A, may be of sufficient structural stability to pass through all the increasing vibratory action without dissociation of its component molecules, until it has passed through the solid, liquid, and far into the vaporous condition, whilst a substance, B, has, what I will call a thermanalytic point, or the point where the equilibrium is broken. If it lies below 100° C., we have dissociation in the liquid condition. A

* Read before the British Association, Edinburgh Meeting, Section B.

* Read before the British Association, Edinburgh Meeting, Section B.

great number of compounds are dissociated above this point, *e.g.*, anomalous vapour density of chloride of ammonium; whilst those dissociated below 100°C . are less common and are much less easy of observation. I find that this dissociation influence is frequently at work when we little dream of it, particularly as regards solutions. I have lately made a well-known natural group of elements my study in connection with these phenomena, *viz.*, the trioxides, aluminic, chromic, and ferric oxides, and find that, as might be inferred, all the compound molecules of these bases are more or less dissociated on heating their solutions. The ferric compounds are the most easily affected: thus the solution of their compounds, if pure, are almost colourless, the slight tinge being in most cases produced by the basic action of the water. By the cautious addition of dilute acid almost colourless solution will be procured (an excess of acid produces also a colouration). On the application of heat this solution becomes gradually darker and darker, until it becomes a dark reddish-brown fluid. If the water bears any considerable proportion to the salt a basic precipitate falls, before it has reached the boiling-point. The relative amount of the water is of the utmost importance in these phenomena, because its basic action lowers the thermanalytic point as I call it. The results of the dissociative influence of heat when a precipitate is not produced is the repartitioning of elements by which a basic and an acid salt is produced simultaneously in the same fluid by the dissociative influence of heat. If these experiments are carried on under pressure, or in the presence of a great excess of water, the dissociative influence is so great from the increased range of temperature that anhydrous oxide of iron can be produced, although in the presence of water.

The compounds of chromium are capable of dissociation in a similar manner, but, in this case, the point of dissociation is higher, and the phenomena are not quite so striking. A pure chromium salt, such as the sulphate when dissolved in water, gives a slightly basic solution from the action of the water. It is for this reason that the cautious addition of the "stylosus" or acid molecule first of all makes it a purer blue—the original solution being violet, with a tinge of green; the addition of an alkali or the heating of the fluid produces a green solution; heated under pressure basic precipitates are procured; or, upon the addition of a large volume of boiling water, the precipitation of the basylous element is determined.

The aluminic molecules at first sight might be considered to differ from the other two, but such difference is only one of degree. They obey exactly the same rule, but, as the thermanalytic point is much higher, and, as there is no chromatic change to mark the dissociative influence of heat, it is difficult to discern this phenomenon. Under the influence of solutions boiling at an increased pressure of 11 or 12 atmospheres, I have not only procured basic salts but gelatinous alumina from the sulphate. As I have explained before, the same results may be obtained by increasing the basic condition of the solution by a very large volume of water. As the pressure retains the boiling-point of the water until we reach the thermanalytic point of the molecule, so the basic action of the water upon the stylosus group lowers the thermanalytic point until we get it within the range of 100°C ., so that the phenomenon can be exhibited at ordinary temperatures. There is no evidence of decomposition in solutions of any considerable strength on boiling, but if a very considerable proportion, 50,000 to 60,000 times its weight of water, is used to the amount of salt, a precipitate is produced at 100°C . This is best seen by passing a beam of electric light through the flask, as the precipitate produced from chloride of aluminium is almost optically invisible in daylight. A beam of electric light impinging upon the light flocculent precipitate at once reveals its existence. Most of the other precipitates can be observed by the eye, but they re-dissolve on cooling.

NOTES ON PHOTOMETRY.

By WILLIAM FOSTER.

Gas Examiner to the Metropolitan Board of Works.

It occasionally happens that three or four experiments made at regular intervals during two hours of any one evening agree so closely that the gas appears to be of the same value each time an experiment is made. The very reverse, however, sometimes occurs, the numbers representing the illuminating power of the gas during the evening differing to the extent of two candles. The readiest explanation of such results as the latter is, that gas of varying quality has been passing through the main at different periods of the evening; and such a view of the case appears to be the only feasible one, when the experiments are known to have been made under similar conditions. By similar conditions it is implied that the gas has the same temperature, and is passing through the meter at an uniform rate, the barometer stationary, and the candles burning the same amount of sperm, or about the same, in each experiment. The first three conditions are obviously necessary. The latter does not at first sight appear to be so, owing to the correction made at the end of each experiment for any variability in the rate of consumption of the sperm. For most practical purposes, this correction for different rates of consumption of the sperm is sufficient—that is, when the candles are burning about the standard quantity. Still it is desirable to restrict its application within as narrow a limit as possible. The instructions of the Gas Referees are, that each experiment shall occupy ten minutes, and that the two candles employed shall consume forty grains of sperm (120 grains per hour). These conditions are rarely ever fulfilled; and it is to wide variations from this standard that my remarks are especially applicable. I have long ago questioned the value of observations taken with candles burning at low rates—say from 33 to 35 grains, and sometimes have not recorded them. The method adopted for arriving at a corrected result is to multiply the sum of the ten photometrical readings taken during the ten minutes by the number of grains of sperm consumed, and to divide this product by two, since two candles are used in the experiment. This process involves the theory that the light emitted from sperm is in simple proportion to the quantity consumed. For instance, *ceteris paribus*, the photometrical readings, based on the law that the intensity of lights is in the proportion of the squares of their distances from the point of measurement, are inversely as the consumption of the sperm. In other words, that any deficiency in the amount of sperm consumed is compensated by a higher reading in the photometer, and *vice versa*, so that the product obtained by the multiplication of the readings and the quantity of sperm consumed, fairly represents the quality of the gas. This does not appear to me to be exactly true, at least not so far as ordinary practice is concerned. During last winter I had a parcel of candles, many of which gave not only low rates of consumption, but also very variable ones. Some of my results at that time were very high; and since then I have incidentally noticed that a low rate of consumption of sperm is in the majority of cases attended with a high number representing the illuminating power of the gas. In order to speak with confidence on this point, a large number of experiments have been made, the majority of which bear out all that I had previously noticed. They were made on consecutive evenings, extending over a week, and one experiment followed the other as quickly as circumstances would permit, the object being to notice whether any difference in the quality of the gas could be detected in such short intervals, when the conditions of the experiment were the same. The following were taken on three succeeding evenings, the same pair of candles being used for all the experiments made on any one evening. The method pursued was slightly different from that recommended by the Referees, and was as follows:—

During the time that the candles were burning in order to be ready for the first experiment, the quantity of gas was adjusted by the meter clock, the meter clock being used only for that purpose. Having the candles burning at the required rate, they were then placed on a balance, and, when the turning point was reached, a clock was immediately started by the right hand. A 40 grain weight was then placed in the balance on the side of the candles, the whole removed to the photometer, and the observations taken in the prescribed time. Towards the end of the 10 minutes the candles were taken out of the photometer, placed on the balance, and, the moment that the turning point was again reached, the clock on the right was instantly stopped. The time which had been required to consume 40 grains of sperm was then noted, and from this was calculated the consumption in 10 minutes. Thus, suppose 625 seconds have been required to burn 40 grains of sperm, then $625 : 40 :: 600 : x$ = the consumption of sperm in 600 seconds (10 minutes), in grains. This method in theory is the true one, the object being to weigh the candles on the two occasions under the same conditions so far as currents are concerned. Apart from this consideration, it has two special recommendations; there is no danger of losing any particles as there is when the candles are blown out, and in the second place the candles are immediately ready for another experiment. The experiments here given were made at a time when the pressure in the main was extremely regular, so much so that, having once obtained the gas passing at the required rate, scarcely any further adjustment was necessary.

Experiments are not wanting which, at first sight, would appear to upset what these now given are intended to show; but such are not numerous. Besides, it must be borne in mind that throughout the whole there was the possibility of a difference in the quality of the gas. Hence the necessity of making a large number of experiments before any satisfactory conclusion could be arrived at. These results may be objected to on the ground that the use of the same candles for showing the effect of different rates of consumption is faulty at the outset, simply because the wicks are not adapted for such varying quantities. I may add that my experience is, that candles will of themselves vary to the extent of several grains. The candles here used were trimmed in order to obtain the different rates, but in no case could I detect anything objectionable in the character of the flame—they did not smoke. These results practically show that the tendency is to report gas above the truth when the rates of consumption are low; or that the amount of light emitted by sperm when burnt in the ordinary way is not simply proportional to the amount consumed, but that it is proportional + a certain quantity. I regret that I have not the means of storing gas of uniform quality, so as to be able by further experi-

ments to arrive at some satisfactory numbers showing the law which regulates this increment to the illuminating power.

The photometer used is that known as Evan's improved form of the Bunsen. It is a rectangular box, 112 inches long, 6.5 inches broad, and about 11.5 inches high. The whole of the interior is lined with black velvet, except the greater portion of the roof, which is rounded, and made of blackened sheet copper. Midway in this box is a fixed diaphragm containing the waxed disc. The box is thus divided into two chambers of equal size, the capacity of one of them being about 4200 cubic inches. In one of these chambers, 50 inches distant from the waxed disc, is a fixed burner for the gas to be tested. In the other box is a sliding support for the candles, this support carrying an indicator which moves along a graduated scale on the outside of the machine. Each chamber is provided with a large door at the side. When an experiment is being conducted, the two chambers are closed during the entire time. The 40 grains of sperm burnt in 10 minutes require 126.2 grains of oxygen from external sources in order to convert the carbon and hydrogen into carbonic acid (carbonic anhydride) and water. The amount of atmospheric air containing this quantity of oxygen is 1768 cubic inches, or nearly one-half the amount contained by the chamber in which the candles are placed. In addition to this a large quantity of air is always carried along with the spent vapours, by virtue of the current which they establish. Now what are the precautions taken for the supply of air, and the exit of the products of combustion and rarefied atmospheric air? Along the whole length of the under part of the machine is a narrow slit from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch in breadth. Air cannot pass into the photometer through this slit without passing twice at right angles, thus avoiding all danger from draughts. This source of air is the only intentional one, and I imagine is sufficient to meet the requirements of both the gas and the candles. It is the means of exit of the heated vapours that appear to me to be faulty. Everyone accustomed to the use of the instrument must have noticed that nearly every time an experiment is made the numerical value of the photometrical readings gradually increases. This increase is such that where the first reading may be 8 the probability is that the 10th will be 9, or 9.5. This ought not to be, as it indicates that the candles do not give the same amount of light towards the end of an experiment that they do at the commencement. It is quite manifest that the gas does not suffer, at least not to the same extent, as the candles, otherwise the increasing value of the readings would not occur. My opinion is that the gas is tested under more uniform conditions than the candles, and for this reason: Immediately above the argand burner is a copper chimney, which at once takes away the heated gases and rarefied air, causing a proportionate influx of cold air through the slit below. The chamber containing the candles is also provided with a similar chimney, equally distant from the waxed disc, namely, 50 inches. The two chimneys, placed as described, not only maintain the symmetrical proportions of the instrument, but, if required, also permit two kinds of gas to be tested in it by burning one at each end. In addition to the two chimneys, one in each chamber, the eaves—so to speak—of the arched copper roof along their entire length admit of the exit of the heated vapours. The two slits, one on each side, are more complicated than the one at the bottom which supplies the air, and consequently the products of combustion of the candles have to pass by a very circuitous route before they can escape. There can be no question that the chimney placed above the gas-flame permits all the impurities to escape at once. The case of the candles is different. When testing 16-candle gas the two candles are then more than 30 inches distant from the chimney, so that its use for the purpose of ventilation is *nil*, or nearly so. The spent vapours and heated air must then escape promiscuously through the slits along the two edges of the roof, which appear to be in-

sufficient for the purpose. At first I was led to suppose that the increased value of the readings was due to an imperfect supply of atmospheric oxygen, owing to the narrowness of the slit supplying the air. But such a view is no longer tenable when one reflects that the supply to a flame eight times the size takes place through the same sized opening, without any apparent deterioration in the value of the flame. And yet there can be no doubt that it is owing to an imperfect supply of oxygen, although caused somewhat differently. The ingress of air is determined by the egress of the heated vapours, so that increasing opportunities of escape for the latter is simply causing a greater supply of the former. It therefore appears to me highly desirable that some form of chimney should be placed over the burning candles, so that they may be under conditions similar to those under which the gas is being tested in the adjoining chamber. If this chimney were constructed with a movable diaphragm, the draught would then be under control. As the instrument is at present worked, the candles are so near the roof that the need of this addition is shown by its very high temperature after the candles have been under it not more than 10 minutes.

ON RECENT INVESTIGATIONS AND APPLICATIONS OF EXPLOSIVE AGENTS.*

By F. A. ABEL, F.R.S., Treas. C.S.

(Continued from p. 104).

NUMEROUS as have been the attempts during the last sixteen years to apply other explosive agents as substitutes for gunpowder in small-arms and even in artillery, no rival of the latter has yet thoroughly established any good claims to success as a propelling agent, except for sporting purposes. Nor does it appear probable, considering the difficulties which have to be encountered in sufficiently regulating the explosive action of gunpowder to adapt it to the heavy artillery of the present day, that even the apparently most controllable of other explosive bodies—gun-cotton—will ultimately prove susceptible of safe application in any larger artillery than field-guns. The ultimate failure of the repeated attempts made in Austria to apply gun-cotton to artillery and small-arms must not, however, be accepted as proof that no results of value are likely to be attained in this direction. A very decided advance had been made towards the successful employment of gun-cotton in field guns, before the Government Committee on Gun-cotton ceased to exist in 1868; and if the experiments on this subject, which were then suspended, as well as those relating to the employment of gun-cotton in military small arms, have not been resumed, it is only because the Committee on Explosives, to whom the further investigation of these matters has been entrusted, has hitherto been fully occupied with the more immediately important investigations relating to gunpowder. Some considerable time was devoted by me, about three years ago, to the production of small-arm cartridges of compressed gun-cotton, suitable for the breech-loading arms of the service, and a system was already at that time pursued with considerable success, of regulating the rapidity of explosion of the material by its impregnation with minute quantities of a non-explosive and otherwise perfectly inert substance, which at the same time imparted considerable water-repellant properties to the cartridge. Experiments with cartridges prepared on this system will be resumed in due course; meanwhile a similar method of treatment has been applied with great success to the production of sporting cartridges made of prepared and lightly compressed gun-cotton, by Messrs. Prentice, to whose energy

and perseverance we are indebted for the firm establishment of gun-cotton as an important explosive agent.

Although gunpowder is still the only propelling agent susceptible of general application, it no longer enjoys a monopoly in connection with some equally important applications to naval, military, and industrial purposes. The very energetic action of potassium-chlorate upon readily oxidisable substances, and the great rapidity and violence of explosion of mixtures of that class, when compared with similar mixtures containing saltpetre, has given rise for many years past to repeated attempts, often renewed in the same directions, to apply that substance to the production of powerful substitutes for gunpowder. Mixtures of it with resin, powdered nut-galls, and other substances of vegetable nature or origin, have been suggested, and in some instances applied to a limited extent in directions where rapidity and violence of explosive action appear to present advantages, as in some kinds of blasting operations; even the old and well-known mixtures of the chlorate with potassium ferri- and ferri-cyanide and sugar, which, for many years past have been described in chemical handbooks as *white gunpowder*, and *German gunpowder*, have been more than once re-proposed of late, not merely as mining agents, but for use in firearms. The practical objection generally raised, and with reason, against mixtures of this class, that they are of detonating character, and consequently more or less dangerous to transport and handle, is always either met or forestalled by the proposal to keep the ingredients separate until the mixture is actually used, as the violent oxidising property of potassium-chlorate renders the production of powerfully explosive preparations possible by crude and rapidly-performed mixing operations, which would be altogether inadequate for the production of useful explosive mixtures with saltpetre. Such a proceeding is, however, inadmissible in naval and military service for several reasons; and the trouble which it would involve at the hands of miners using such preparations will probably always lead them to forego any advantages which might result from their employment, and either to adhere to gunpowder or to employ other materials supplied in the form in which they are actually to be used, even though considerable risk of accident may be incurred with these. Some of the preparations of this class, which, disguised by fancy names, occasionally find their way into miner's hands, are of so dangerous a character that it amounts to little short of deliberate criminality to endeavour to find a sale for such materials. Even mixtures consisting chiefly of potassium-chlorate and sulphur have been recently recommended as useful and safe mining agents. It need scarcely be said that a mixture of these substances is liable to explosion if submitted to a very slight friction or concussion; and although their sensitiveness to ignition may be very considerably reduced by the admixture of other substances, such mixtures will always be extremely liable to accidental explosion during the process of tamping, or unless handled with very great and constant care. A special application of the mixture of potassium-chlorate and sulphur, which merits brief notice, was made for war purposes in France at about the time of the late Exhibition. By converting the mixture into a paste, and then drying it, hard masses of the explosive agent can be produced, which are made to fit shells of lead, and afterwards completely enclosed in the metal by the operation of "spinning." A small-arm projectile is thus produced, which may be safely fired from a rifle, but which explodes with fearful violence even upon penetrating flesh, producing the most appalling wounds. It may be remembered that an account was published about a year ago of trials made in London upon horses with explosive bullets of this kind, the results of which established the success of the bullet as one of the most fearful destructive agents ever applied; but the agreement entered into long before the late war by the principal nations not to employ explosive bullets, has precluded any use being made of this ingenious mode of safely applying so highly detonating a mixture. It need hardly

* A Lecture delivered to the Members of the British Association at Edinburgh, August, 1871.

be stated that the conditions essential to safety, which can be readily fulfilled in enclosing a material of this kind in a leaden projectile, and firing it from a small-arm, do not bear comparison with those which arise when shells are fired from guns, even of small calibre.

The discovery of a more violent explosive agent than gunpowder, which may be employed as a charge for shells without any risk of accidental explosion resulting from the concussion to which they are exposed when the gun is fired, has been considered a desideratum for some years past. A few experiments were made by the late Committee on Gun-cotton upon the employment of that substance in shells, and spherical shells were safely fired from a mortar of 13 inches calibre, but disastrous results were obtained when this material was used as the charge of lead-coated and studded elongated projectiles fired from rifled guns. A few were safely fired, but, without any apparent alteration of conditions, others burst in the gun, and instead of simply indenting and scoring the bore, as would have been the case if a shell charged with powder had burst prematurely, one gun was rendered perfectly unserviceable by the violence of the explosion, and another was burst, the fragments being projected many hundred yards. Further systematic experiments have been continued for Government from time to time, with a view of discovering a safe and powerful explosive agent for shells. The relative disintegrating and scattering powers of a large number of explosive agents has been determined, in the first instance, by filling cast-iron shells of a particular calibre with the different materials; bursting these in a chamber of great strength, lined with wood; carefully collecting all fragments which could afterwards be found on the floor, and which could readily be extracted from the walls of the chambers, and determining the individual and total weights of these. In this way the extent to which the different shells were broken up by the explosion was correctly ascertained, and many explosive agents, for which great power had been claimed, but which proved to be not greatly superior to gunpowder, were eliminated, the most powerful being selected for further experiment. In illustration of the results thus arrived at, it may be stated that, when a shell weighing 16 lbs. 1 oz., filled with powder, was burst, all the fragments were readily recovered; they amounted to eighteen, including the plug of the shell, and of these twelve weighed above 2 ozs. and under 2 lbs., and only one fragment weighed less than 1 oz. Upon bursting a shell of the same kind and weight, filled with a mixture of potassium-chlorate and potassium-picrate, 100 fragments were recovered, and these weighed altogether only 2 lbs. 6 ozs., nearly 14 lbs. of the shell having been dispersed in fragments too minute to be collected individually. Only one of the recovered fragments weighed more than 8 ounces, and ninety-three weighed less than 1 oz. It need scarcely be stated that such a disintegration of the shell would be far too considerable to render the latter of value as a destructive missile, but the result showed that a small proportion in weight of this potassium-picrate powder if it could be used in shells, would suffice to produce the desired breaking up of the shell and violent scattering of the fragments, and that, therefore, the thickness of metal of the shell, and its consequent destructive power, might be very considerably increased. The chilled iron or Palliser shells, which, being of considerable thickness, hold comparatively small charges of powder, would obviously be rendered much more destructive as shells, by substituting for the powder-charges an explosive agent even considerably less violent in its action than the one just cited as an example.

The shell experiments above referred to were followed by a series of another kind, instituted in the first instance for the purpose of determining the relative susceptibility to explosion, by concussion or other mechanical causes, of gunpowder, and of the explosive agents selected from the results of previous experiments as most promising in their nature. These experiments consisted in interposing definite quantities of the materials between a flat

brass plates, placing them upon a rigid support, and allowing a weight to fall upon them from different heights. It soon became apparent that by varying the weight employed, and the surface and thickness of the layer of explosive material operated upon, some interesting and probably very useful results could be obtained. These experiments have therefore been considerably extended, and I trust shortly to have completed them sufficiently for publication of the results. It should be stated that some similar experiments were instituted by MM. Girard, Millot, and Vogt, during the siege of Paris last year, with mixtures of nitro-glycerine with a variety of solid and liquid substances of inert character, for the purpose of discovering the safest and most suitable media for the application and preservation of that explosive liquid. A communication made at about the same time to the French Academy of Sciences, by M. Champion, on the application to war-purposes of the mixture of nitro-glycerine and siliceous earth, well-known as dynamite, contains a statement to the effect that a shell filled with dynamite was safely fired from a gun at Mont Valérien, and the somewhat hasty conclusion is drawn from this single result that dynamite may be safely used in shells. More conclusively favourable results on the employment of nitro-glycerine in shells were obtained at Shoeburyness three years ago, when six shells (the entire number experimented with) were successfully fired, containing charges of a solid nitro-glycerine preparation, in which a mixture of pulped gun-cotton and saltpetre is made the vehicle for the employment of the liquid, and which therefore consists entirely of highly explosive material. The power of this substance had been previously demonstrated by numerous experiments, among which a charge less than one-third that of the full powder charge, mixed with sufficient sawdust to fill the chamber of a shell, burst the latter into ten times the number of fragments obtained with gunpowder. Promising as these results were, it was deemed advisable to seek for some other explosive agent than a nitro-glycerine preparation as the material for shell-charges, for two reasons—firstly, because the well-grounded confidence in the safety of nitro-glycerine and its preparations, essential to their employment in naval and military service, does not yet exist; and secondly, because the explosive force of these preparations, as illustrated by the one experimented with, appeared considerably to exceed that required in connection with the most general application of shells. Eventually, one of the salts of trinitro-phenic acid or picric acid was found to furnish an explosive mixture, which, as far as experiments have been carried, has proved to possess all the essential qualifications of a material applicable in the service as "shell-powder."

Picric acid, or carbazotic acid, as it was first called, is one of the earliest explosive substances of organic origin known, having been discovered as far back as 1788. It is produced by the action of nitric acid on a variety of organic substances. One of the earlier methods of obtaining it readily was by the action of nitric acid on indigo; but a comparatively abundant source of it was pointed out about thirteen years ago by Stenhouse, who readily produced it in large quantities by acting with nitric acid upon the resin *Xanthorrhoea saxtilis*, which was imported in considerable quantities from Botany Bay. Since the manufacture of phenol or carboic acid from coal-tar has become developed, picric acid has been very extensively produced from that substance, and, as a cheap and brilliant yellow dye, has become an important article of commerce.

The acid itself does not explode, but burns quickly with a bright flame; its salts are all more or less powerfully explosive, and detonate when struck. The potassium salt is that most easily prepared, on account of its very slight solubility in water. It is also one of the most highly explosive. When mixed with oxidising agents, and especially with potassium-chlorate, it furnishes very powerful explosive materials; indeed, the chlorate mixture approaches nitro-

glycerine and gun-cotton nearly in violence of action than any other explosive agent produceable on a practical scale. This mixture is, however, so susceptible of detonation by friction or concussion as not merely to render its employment in shells impossible, but also to preclude its application to any purpose without the adoption of very special precautions. Other mixtures containing potassium-picrate have been made the subject of experiment, especially in Paris, where so-called "*poudre picrate*" or *poudre Designolle*, composed of potassium-chlorate, potassium-picrate, charcoal, and saltpetre, was prepared and experimented with upon a considerable scale about three years ago, as a substitute for gunpowder in firearms, and for other purposes. A fearful accident at a factory in Paris, where large quantities of the potassium-picrate were manufactured, led to the abandonment of these experiments; but there appears little doubt that picrate preparations were included among the agents of destruction employed by the Communists in the recent struggle at Paris. In the course of the experiments with shells containing various explosive substances, to which reference has just now been made, I was led to examine the properties of mixtures of ammonium-picrate with oxidising agents. This picric compound, which may be readily prepared upon a large scale, differs importantly in its behaviour, when exposed to heat, from the potassium-picrate, and from several other salts of this acid. When heated over a flame it fuses, sublimes, and burns without any tendency to explosion, while the potassium salt detonates under the same conditions. The latter also detonates somewhat violently when submitted to a moderate blow, whilst it is difficult to obtain evidence of detonation of the ammonium salt when struck sharply and repeatedly. A mixture of the potassium salt with saltpetre, though less susceptible to explosion by a slight blow than the chlorate mixture, is yet powerfully detonating; while a mixture of ammonium-picrate and saltpetre requires a violent blow to develop slight and partial detonation, and exhibits no tendency to ignition when submitted to very severe friction, which would at once explode the least sensitive of the explosive mixtures proposed as substitutes for powder. When flame is applied to particles of the mixture of saltpetre and the ammonium salt (to which I have given the distinctive name "*picric powder*,") the individual particles deflagrate with a hissing sound like that of the sudden escape of steam, and the deflagration has little or no tendency to spread to contiguous particles; but if the mixture is strongly confined, as in shells, it explodes violently, and exerts a destructive action, less formidable than that of gun-cotton, nitro-glycerine preparations, and potassium-picrate powder, but considerably greater than that of gunpowder, and therefore likely to prove a valuable substitute for the latter when greater violence of action is desired with shells of small capacity. A number of shells charged with picric powder have been fired without a single casualty from guns of different calibres, ranging to the 9-inch gun with the employment of a battering charge of 43 lbs. of R. L. G. powder. The safety of this substance is therefore considered sufficiently established to warrant the institution of thorough trials of its powers as an explosive agent for shells. It is a curious and important circumstance connected with this mixture, that though ammonium-picrate and potassium-nitrate undergo mutual decomposition, with production of the deliquescent ammonium-nitrate, if the two be dissolved together in water, the addition of sufficient water even thoroughly to moisten the mixture appears to induce no such change, as the latter, when dried again, has no increased tendency to absorb moisture from the air, which it scarcely does to the same extent as gunpowder. The picric powder is therefore quite equal in permanence to gunpowder, and as water may be used in incorporating the ingredients without any detriment to the stability of the mixture, its preparation is, at any rate, not more dangerous than the manufacture of gunpowder, and it may be safely submitted to the

pressing and the granulating processes which are applied to the latter. As, moreover, the cost of picric powder, as compared to its power, is not considerable, this explosive agent is now recognised as susceptible of advantageous application to service purposes, provided its sufficient superiority over powder in regard to violence of action is satisfactorily established. It should be stated that, some time after experiments had been in progress with this material, at my instigation, it came to my notice that a Frenchman, M. Brugère, had been also experimenting with mixtures containing ammonium-picrate, and had suggested the employment of a saltpetre-mixture as a general substitute for gunpowder. It does not appear that any steps were taken in France at the time to submit this proposal to practical test; and there is good reason to believe that, as regards naval and military uses, the picric powder is hardly likely to offer special advantages, excepting as a safe material for use in shells.

The successful application of the remarkable explosive liquid, *nitro-glycerine*, which is primarily due to the ingenuity and untiring perseverance of Mr. Alfred Nobel, and which has been developed chiefly within the last seven years, presents several points of great interest. Though this liquid was discovered as far back as 1847, Nobel was the first to attempt its practical application. His original proposal was to apply it in conjunction with gunpowder (*i.e.* that of adding to the explosive force of the latter when used in shells, and for mining purposes, by impregnating the grains with the highly-explosive liquid) was not attended by any tangible success. He then appears to have proceeded upon the idea that by raising some small portion of a charge of nitro-glycerine to a temperature sufficiently high for its violent decomposition, he might succeed in producing an initiative explosion of that part of the charge, which would be transmitted to the remainder, and he was thus eventually led to employ a small charge of a detonating material, such as percussion-cap composition, to bring about the violent explosion of the liquid. This ingenious expedient, the precise *rationale* of which I had afterwards occasion to investigate in its general application to the development of the action of explosive substances, was the foundation of the successful employment of nitro-glycerine in mining operations. The existence of several most serious obstacles to the use of nitro-glycerine in its pure liquid condition was, however, soon practically demonstrated—in several instances, indeed, by most disastrous accidents, not easily effaced from memory, and the ingenuity of Mr. Nobel was consequently taxed to devise some method of promoting safety, and also certainty of action, in the employment of this powerful explosive agent. These ends were attained, at any rate to a great extent, by mixing nitro-glycerine with some solid substance of perfectly inert nature and of absorbent character, through the medium of which the liquid is susceptible of employment in a condition assimilating to that of other explosive agents in practical use. The vehicle employed by Nobel is a light siliceous earth, known in Germany as "*kieselguhr*," which may be mixed with about three times its weight of nitro-glycerine without becoming more than moist to the touch, and is therefore readily susceptible of manipulation as a solid material. This mixture, to which the name of *dynamite* was given by Nobel, is also specified to contain a small proportion of alkaline matter, to be added for the purpose of counteracting any tendency to the spontaneous development of free acid in the nitro-glycerine. Dynamite is as readily susceptible of explosion through the initiative agency of a detonating fuse as nitro-glycerine itself; and though it obviously cannot be so powerful an explosive agent as that substance when successfully applied in its undiluted condition, its destructive powers are still very greatly in excess of those of gunpowder; and this fact, together with the circumstance that, when properly applied, it does not need confinement for the development of its explosive force, and that it may be employed, with certain precautions, in damp blast-holes, without great

detriment to its action, has led to its gradually becoming very extensively applied to industrial purposes. Certain defects are inherent in the material, such as its losing its susceptibility to detonation by the ordinary means at a low temperature, and the tendency of the nitro-glycerine to partial separation from the siliceous earth during transport and storage; but, in balancing its advantages against those of other explosive agents, the special defects of these have also to be taken into account; so that, provided the uniform stability of the material becomes firmly established, and the apprehensions as to its comparatively dangerous character, to which certain accidents have given rise, are allayed by further experience in its storage and use, and possibly by improvements in its manufacture, a high position may be assigned to dynamite among the most useful explosive agents of the present time.

Several other methods of applying nitro-glycerine as a destructive agent have been brought to public notice since Nobel's dynamite first attracted attention. Among the proposed preparations, the most recent, and one for which special power and virtues have been claimed, is the substance to which its inventor, M. Engels, has given the name of *lithofracteur*, and which contains in addition to nitro-glycerine and an absorbing medium of the description used in dynamite, some proportion of other explosive materials (such, for example, as the constituents of gunpowder). This substance, which appears to have been applied to a limited extent by the Prussians during the recent war, is of a plastic and almost pasty nature, and is employed in the form of rolls made up in paper, which absorbs some proportion of the nitro-glycerine. Its tendency to yield to pressure, even when suddenly applied, renders its accidental explosion by mechanical force a matter of very considerable difficulty, probably more so than in the case of dynamite. As regards its claims to superiority in point of safety and power over the latter and other similar preparations, they are still matters of dispute, and their validity can only be satisfactorily determined by careful comparative experiment.

During the siege of Paris a dynamite factory was established in the outskirts of the city, and, in the absence of the particular siliceous earth which Nobel employs in its preparation, MM. Girard, Millot, and Vogt made a series of experiments, already alluded to in this lecture, with a view of ascertaining what substance could be best employed as a substitute for that absorbent material; their results indicated that, in addition to precipitated silica, the best media to be used are kaoline, tripoli, alumina, or sugar, the latter presenting the special feature that the nitro-glycerine can be rapidly separated from it by addition of water, a supposed advantage which Mr. Horsley had previously claimed for a mixture of nitro-glycerine and alum, but which may obviously constitute an important disadvantage in special applications of these mixtures—the tendency to separation of the liquid nitro-glycerine from them in wet blast-holes being a decided defect.

Sawdust and similar absorbent materials have also been used as vehicles for the application of nitro-glycerine, especially in America, under the name of *dualine*; and another preparation of nitro-glycerine, to which some years ago I gave the name *glyoxiline*, and with which some very effective blasting and engineering operations were carried out, consists, as already stated, of a mixture of gun-cotton pulp and saltpetre, which is saturated with nitro-glycerine. In the preparation of this material, one of the objections to the use of nitro-glycerine, arising out

of its poisonous nature, and the readiness with which it is absorbed into the system, was, at any rate, partially met by providing the granules or masses of glyoxiline with a coating of some impermeable material. The injurious effects of nitro-glycerine upon the health of those constantly handling and employing it or its preparations, must unquestionably be frequently productive of serious results, but are scarcely likely to interfere with their industrial applications, as it is well-known that risk of accident or of permanent injury to health will not deter men from persevering in the continuous use of means which may add to the productiveness of their labour.

(To be continued).

A LARGE INDUCTION COIL.

We give herewith a woodcut taken from a photograph of an induction coil, built last summer by Mr. E. S. Ritchie, of Boston, for Dr. Morton, President of the Stevens Institute of Technology, about which the latter gentleman writes us very favourable accounts. He has, during the past winter, had occasion to use the instrument constantly, and to transport it to Washington, Baltimore, Philadelphia, New York, and elsewhere, and has never found it fail of the most satisfactory performance. The entire weight of the coil without the condenser, which is in the separate base shown in the front of the woodcut, is 166½ lbs.

Its length from end to end of caps over primary coil is 40 inches, and its height to the upper surface of the long horizontal strip is 18½ inches. The length of each of the secondary bobbins is 13 inches, and their external diameter is 9 inches.

The primary wire is 200 feet long, and 0.1655 of an inch or ⅓ inch in diameter; its electrical resistance is 0.13 of an Ohm. The secondary wire is 234,100 feet, or about 44½ miles, long, 0.007 of an inch in diameter, and weighs 44½ lbs.; its resistance is 404,000 Ohms. The condenser contains 325 square feet of coated surface.

The battery used with this coil consists of three glass jars, 10 inches diameter, and 12 inches high, into which are lowered by a windlass fifteen plates of zinc and fifteen of carbon, each 6×9 inches. The exciting liquid is the usual mixture of potassium bichromate and sulphuric acid. This battery has proved itself admirably efficient and reliable.

The performance of the coil is as follows:—With the above battery freshly charged and immersed 1 inch it gives freely sparks 21 inches long in air, and with the cascade battery of twenty coated panes, described by Prof. Morton in the *CHEMICAL NEWS* (vol. xvii., p. 149), it gives white Leyden jar sparks 14 inches long.

With a large Leyden jar its spark is reduced to 2½ inches, but the light then afforded is sufficient to illuminate well a zoetrope disc 4 feet in diameter, and its sound is almost deafening.

Solid blocks of glass, 3 inches thick, can be pierced by the spark from this coil, and when the spark is repeated it takes a new path each time. When used to illuminate a Gassiot's cascade, a secondary condenser or cascade battery (as described by Prof. Morton in the article alluded to above) being in circuit, the effect is so brilliant as to allow of the use of this illustration in the largest public buildings. The entire coil is divided in the middle, so that it can be coupled for quantity effects.

EXAMINATION OF SAMPLES OF CHLORAL HYDRATE.*

By M. M. PATTISON MUIR, F.C.S. Glasgow.

As chloral hydrate has of late become a somewhat extensively used medicine, and as the purity of the compounds used in pharmacy is a matter affecting the interests of many, there was most properly noted in the circular of the British Pharmaceutical Conference among the subjects for investigation—"The Purity of the Chloral Hydrate of Trade."

Chloral hydrate, by the action of caustic alkalis, is broken up into chloroform, and a formate of the metal of the alkali employed; thus with caustic potash—

In this investigation I have endeavoured, in the case of each sample examined, to answer the following questions:—

(1). Does the sample yield, upon treatment with caustic alkali, such a percentage of chloroform as might reasonably be expected?

(2). Does the sample contain any, or any appreciable amount of, chloral alcoholate?

And, further, with regard to commercial chloral hydrate generally, I have endeavoured to show which samples, judging from their appearance and physical characters, are to be regarded as purest. And, lastly, I have sought to give an answer to the general question—Is the chloral hydrate now sold by druggists of a fair average purity?

Pure chloral hydrate is easily soluble in water; upon heating, it dissolves, leaving a perfectly clear fluid. Chloral alcoholate, on the other hand, heated with water, melts, but does not dissolve, and solidifies again, beneath the water, upon cooling. Pure chloral hydrate, again, with strong sulphuric acid, floats on the surface of the acid, and, on heating, slowly melts, forming a clear layer of liquid with the heavier acid beneath, with no browning or discolouring of the acid; chloral alcoholate colours the acid brown upon being treated in a similar manner. With nitric acid (25 per cent strength), pure chloral hydrate gives, on applying heat, little or no reaction; alcoholate gives violent reaction, red fumes being given off.† The boiling-point of pure chloral hydrate is 96°–98° C.; of alcoholate, 115° C.

The process adopted for estimating the CHCl_3 yielded by each sample was that described by K. O. Müller (CHEMICAL NEWS, vol. xxiii., p. 113), viz.:—Into a tube, graduated from the bottom in c.c., was introduced a certain known quantity of the sample; pure caustic potash solution of medium strength was then added, and, after standing ten to fifteen minutes, the tube and its contents were thoroughly shaken until all the chloral hydrate was dissolved. The tube being securely corked was then set aside, and, after three to four hours, the number of c.c. of chloroform which settled to the bottom of the tube was read off; this was multiplied by the sp. gr. of chloroform—the figure taken being 1.5—and so was obtained the percentage of chloroform yielded by the sample under examination. The results are embodied in the following table:—

Sample. Appearance.	Behaviour on heating with water.	Behaviour on heating with strong sulphuric acid.	Behaviour on heating with dilute nitric acid.	Boiling-point.	Percentage of CHCl_3 on treating with KHO.
1. Large pieces, crystalline, slightly moist to the touch, strong pungent odour.	Easily dissolved, nothing crystallised out on cooling.	Melted on the surface, no discolouring of the acid.	Dissolved, no fumes given off.	97°	67.70
2. Semi-transparent, not perfectly pure white, slightly moist, crystalline.	Do.	Do.	Do.	96.5°–97°	65.99
3. White cakes, no definite crystalline structure, falling easily to powder, moist to the touch.	Do.	Do.	Do.	96°–96.5°	68.07
4. Very pure white small non-transparent pieces, crystalline.	Do.	Do.	Do.	97°–97.5°	68.15
5. Had white cakes non-transparent and non-crystalline, seemingly dry.	Do.	Do.	Do.	97.5°–98°	70.83
6. Small round transparent pieces, no needle-shaped crystals, very slightly moist.	Do.	Do.	Do.	96.5°–97°	71.02
7. Small non-transparent pieces with very little crystalline structure.	Do.	Do.	Do.	97°–98°	67.71
8. Tolerably large pieces, crystalline, much more moist than any others.	Do.	Do.	Do.	96°–96.5°	60.98

Theoretically, pure chloral hydrate should yield, on treatment with caustic alkali, 72.20 per cent of CHCl_3 .

From these results I would conclude—

(1). Generally, the samples were of a fair average quality.

(2). None of them, so far as I may infer from my experiments, contained chloral alcoholate.

(3). The purest was that sold in small transparent pieces, nearly dry to the touch, exhibiting no needle-shaped crystals, and not having a very pungent odour.

(4). The samples varied in the amount of chloroform yielded by each, chiefly, it seems to me, on account of the time they had stood in the shop—chloral hydrate easily

* Paper read before the British Pharmaceutical Conference, Edinburgh Meeting.

† Year-Book of Pharmacy, 1870, pp. 112–113.

absorbing moisture, and the stoppers being frequently removed, those samples which had been some time in the shop must necessarily be more moist than those newly received from the maker. This view is confirmed by the amount of chloroform yielded by Samples 5 and 6, which were obtained from wholesale dealers, and had not, therefore, been exposed to the varying fortune likely to meet them while standing on the shelves of a druggist's shop. Generally, these experiments show that the chloral hydrate now sold by druggists is of fair average quality.

SCHOOLS OF CHEMISTRY.

THE following information arrived too late to appear in our "Students Number":—

BERNERS COLLEGE OF CHEMISTRY, 44, BERNERS STREET, W.—Conducted by Professor E. V. Gardner, F.E.S., &c. The course of study in each instance is directed to the express want of the pupil, or according to choice. A course embraces thirty or thirty-five lectures, of a practical character, of about one and a half hours' duration. The usual practice of a Laboratory can be obtained with every convenience, under the immediate direction and guidance of Professor E. V. Gardner. An evening class in practical chemistry for laboratory work, meeting for two hours twice each week during one term; fee, two guineas, to be paid in advance.

LADIES' MEDICAL COLLEGE.—The Ladies Medical College, established by the Female Medical Society in order to teach to educated women the theory and practice of Midwifery and the accessory branches of medicine. *President.*—Lord Shaftesbury. *Hon. Sec.*—Dr. James Edmunds. The eighth annual session will commence on October 2nd, 1871, and extend to April, 1872, with a vacation of two weeks at Christmas. The lectures will occupy the afternoons of the Mondays, Tuesdays, Wednesdays, and Fridays, from 3 o'clock till 5. *Elementary Materia Medica.* (Teachership now vacant.) *Elementary Chemistry.*—Mr. J. A. R. Newlands. Fee for two sessions' attendance upon the lectures on midwifery, anatomy, and physiology, medical science, and hygiene, £10 rs. Fee for each of the extra courses, one session, £1 1s.; two sessions, £1 11s. 6d. Further details as to the objects and operations of the society, and prospectuses of the college, may be obtained by letter to the Lady Secretary, 164, Great Portland Street, W.; or from the Hon. Sec., 4, Fitzroy Square, W.

THE HARTLEY INSTITUTION, SOUTHAMPTON.—*Lecturer on Chemistry.*—A. W. Bickerton, F.C.S., A.R.S.M. *Assistant.*—G. Gray. *Junior Class.*—A Course of about thirty Lectures is given during each term. On Mondays, Wednesdays, and Fridays, from 10 till 11 a.m. *Senior Class.*—Mondays and Thursdays, at 11 a.m. The Junior Class is devoted to a general outline of the theory of chemistry, illustrated by experiments and demonstrations. In the Senior Class students are taken through the applications of Chemistry to the Arts, Analysis, &c., receiving at the same time practical instruction in the Laboratory. Fees for the Senior Class, £2 2s.; for the Junior, £3 3s. per term. The Laboratory is open daily from 10 till 4, except on Saturdays, when it closes at 1, for instructive and practical work. Fees may be known on application. Evening Classes in theoretical and practical chemistry, are held during the winter session.

CORRESPONDENCE.

ALUM IN BREAD.

To the Editor of the Chemical News.

SIR,—I was surprised the other day on reading the report of a lecture on this subject, delivered by Dr. Carter Moffat before the Chemists' and Druggists' Association, at Glas-

gow, in January last, to find him stating that alum and logwood gave a dark red colour, which is directly at variance with the well-known characteristics of the mixture of those substances, as given in every work on chemistry and dyeing to my knowledge for upwards of 40 years, and until some higher authority can be adduced to support such a statement I must decline to accept it, having invariably found that a deep purple or violet blue is the result.

Dr. Moffat's experiments were made at night time, but I fancy if he examined his specimens in the morning when the colour became fully developed, he must have found that all those which really contained alum went blue, as of course they ought to do. Surely there must be a mistake somewhere.—I am, &c.,

JOHN HORSLEY.

The Laboratory, Cheltenham,
September 9, 1871.

"THE ONENESS OF MATTER."

To the Editor of the Chemical News.

SIR,—Professor William Thomson has given to the world an hypothesis by which he accounts for the origin of life on this earth. On this hypothesis we are to consider the endless variety of plants and animals derived from a few simple forms received meteorically. It is indeed a "prodigious step." I conceive as possible that all matter—simple or compound (so called)—is constituted of one element under different molecular forces. The step from one simple form of matter to all known and unknown compounds is less prodigious than that assumed by Sir W. Thomson. Yet the two cases are somewhat parallel.

Compounds have, in general, no resemblance in properties to the elements which constitute them. If a force, or forces, can cause the union of two elements, and the compound formed is no likeness of its constituents, may not a force, or forces, act on one matter or element, and the resultant bear no likeness to the original matter! See how unlike carbon as charcoal, and carbon as the diamond are, and yet they are one matter. By combustion both give carbonic acid gas.

Thus all the 65 elements, so viewed, would be the same matter actually, but each under different forces; the forces engaged so operating as to give to each different properties. And it would be easy to rise from simple to compound matter; a compound being formed by a uniting force between two or more such differently operated upon portions of elemental matter. On this hypothesis, if all forces were withdrawn so as to leave all the ultimate particles in contact, matter would be reduced to simplicity. Finally, in relation to this subject—to use Professor Thomson's words—"All I maintain is, that it is not unscientific."—I am, &c.,

CHAS. THOS. KINGZETT.

Putney.

THE GUN-COTTON EXPLOSION.

To the Editor of the Chemical News.

SIR,—Having carefully considered the evidence, as reported in the public papers, it appears to me that the most probable cause of the explosion of gun-cotton at Stow market has not been suggested by any of the witnesses examined.

I believe it to have arisen from the effect of gradually accumulated heat from the vaporising action of the unusually heated magazine on damp gun-cotton.

When this substance was first introduced I experimented extensively on its manufacture, and soon found the importance of perfect neutralisation of acid, and of peculiar care in drying.

With rapid ventilation, at a high temperature—over 300°—it could be dried without danger, but at a temperature even as low as 100° ignition would take place most

readily if the moisture, as soon as vaporised, were not removed by ventilation.

Evidence has been given of the malicious introduction of sulphuric acid, but it has not been shown that, although it may promote decomposition, it has, in the case of the discs examined, increased their liability to ignition. It is, however, probable that the sulphuric acid may have caused the absorption of moisture, which, on the heating of the magazine during the hot weather, may have been vaporised, and thus the temperature within the gun-cotton may have gone on increasing until the explosive point was attained. In the course of evidence it did appear that the month of August had been recognised as peculiarly liable to explosions.

In the *Chemical Gazette* some time since, I called attention to the fact that I had repeatedly ignited fibrous peat, shredded into small portions, by placing it, while damp, in a partially closed vessel in a position where the bottom of the vessel could not have attained a higher temperature than 120° F.

I could always prevent the ignition by stirring the mass sufficiently to allow of the dissipation of the vapour formed within the mass of fibrous matters.

Having regard to these facts, I applied the principles suggested with great success to several practical purposes; and I took every opportunity of cautioning persons using drying processes on hydro-carbonaceous bodies, whether fibrous or otherwise.

I predicted disastrous explosions which occurred in two gunpowder manufactories in this neighbourhood. Want of attention to the caution given issued in the closing of both of the factories.

If ordinary hydrocarbons, such as peat, sawdust, hemp, starch, &c., be liable to ignition at such low temperatures, what may not be expected of similar substances when associated with other matters greatly increasing their tendency to ignition.

The manufacture of gun-cotton may, no doubt, be safely carried on by carefully ventilating the driers, using every precaution suggested by the knowledge of these facts, such as the employment of only a low temperature, with an amount of ventilation largely in excess of ordinary requirement to prevent danger from changes of atmospheric conditions.

It becomes, however, a very serious question whether the use of gun-cotton may be maintained with the knowledge of the extreme danger arising from its becoming accidentally moistened, and its consequent liability to heating up to the point of ignition by the ordinary increase of atmospheric temperature. This difficulty may possibly be overcome by waterproofing the perfectly dried gun-cotton. I have succeeded in waterproofing gunpowder, but I have not had the opportunity of experimenting on gun-cotton. I do not anticipate any great difficulty in so doing, especially as in the form of discs it is greatly facilitated.—I am, &c.,

ROBERT OXLAND, F.C.S.

Compton Gifford, Plymouth,
September 8, 1871,

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 13, 1871.

From the protocol of the meeting of this Society we quote the following:—Prof. A. W. Hofmann exhibited to the members a series

of photographic pictures representing views of the new chemical laboratory built at Pesh (Hungary), and sent to the *savant* just named by Dr. von Than. It appears, from the brief explanatory paragraph devoted to this subject, that this new laboratory is in every respect an excellent, yet somewhat improved, copy of the celebrated Berlin laboratory. All members of the Chemical Society above alluded to are politely requested to send in their *carte de visite*, signed with their names, to Dr. C. Scheibler, 24, Alexandrinen Strasse, Berlin, in order to complete the photographic album of the Society. All books, pamphlets, &c., intended to be presented to this Society are requested to be sent to the same address.

The number above mentioned contains the following original papers and memoirs:—

Application of Polarised Light for Determining the value of the Cinchona Barks.—O. Hesse.—This paper is in reality a critical review of a paper published by Dr. J. E. de Vry (*Journ. Pharm. Soc.*, No. 53, p. 1, 1871), "On the Adaptability of the Strong Action most of the Cinchona Alkaloids possess upon Polarised Light for the purpose of Estimating the Value of the Cinchona Barks." The author of this paper points out the great difficulties which, in various respects, stand in the way of such an application, and reminds, among other matters, that, beside quinine and cinchonine, the barks alluded to contain, as first stated by Dr. De Vry's discoveries, other alkaloids, the action of which, as regards polarised light, is almost unknown.

Chemical Studies on the Alkaloids of Opium.—O. Hesse.—This lengthy essay treats, in the first place on the mode of preparation, and next on the properties, of some of the more recently discovered alkaloids of opium, viz.:—Cryptopine, $C_{21}H_{22}NO_8$, fuses at 217°, readily soluble in chloroform, not so in ether, difficultly so in alcohol, has a strongly alkaline reaction, and forms, with acids, salts, most of which crystallise; protopine, $C_{20}H_{21}NO_8$, fuses at 202°, is almost insoluble in ether, but difficultly soluble in alcohol; laudanone, $C_{21}H_{27}NO_7$, crystalline in prismatic shape, readily soluble in alcohol and ether, fuses at 89°, and forms with HCl a very difficultly soluble salt; hydrocotarnine, $C_{22}H_{25}NO_8$, fuses at 50°, is crystalline, readily soluble in ether and alcohol, and exhibits, with strong sulphuric acid, the same reaction as does narcotine. The author calls attention, at length, to the peculiar reactions which these and other (codeine, codamine, and laudanine) opium alkaloids exhibit with pure and impure (that is, containing a trace of oxide of iron) strong sulphuric acid at 20° and at 150°. These reactions are so marked by the peculiar colourations which ensue that these bodies may be thereby readily recognised and detected. While space forbids us to give here the full details, we quote, as instances, the following:—

	Pure acid dissolves—		Acid containing iron dissolves—	
	At 20°.	At 150°.	At 20°.	At 150°.
Codeine	Colourless.	{ Dirty green.	Blue.	{ Dirty green.
Codamine	Colourless.	{ Dirty red to violet.	Deep greenish blue.	{ Deep violet.
Laudanine	{ Very faint rose-red.	{ Dirty violet-red.	{ Brownish red akin to solution of nitrate of cobalt.	{ At first green, next deep violet.

Contribution to our knowledge on Benzyl-Ether.—F. Sinitis.—The contents of this paper treat mainly on the behaviour of benzyl-ether with the haloids. By the direct action of chlorine, bromine, &c., upon the ether just named, either at the ordinary temperature or by the aid of heat, no substitution products are formed; while, as regards benzyl-phenyl-ether, substitution products are only formed under peculiar conditions. When benzyl-methyl-ether or benzyl-ethyl-ether are treated with dry chlorine at the ordinary temperature, there is formed oil of bitter almonds, C_6H_5COH , and chloromethyl, chlor-ethyl, and benzyl-ethyl-ether yields, under these conditions, C_6H_5ClCOH and chloroethyl. The benzyl-phenyl-ether—

does not exhibit, with the haloids, any stability in forming substitution products.

Miscellaneous Notices.—L. Henry.—This lengthy paper, filled with a large number of extensive formulae, is divided into the following sections:—On the isomerism of the glycerine derivatives of the formula $(C_2H_5)_3X_3$. On various glycerine derivatives—chloro-iodhydrine, $(C_2H_5)_2ClI$; chloro-bromo-iodhydrine, $(C_2H_5)_2ClBrI$; chloro-brom-nitrin, $(C_2H_5)_2ClBr(NO_2)$; chloro-nitro-sulphuric acid glycerine, $(C_2H_5)_2Cl(NO_2)(ISO_3)$; bichloroacetin, $(C_2H_5)_2Cl_2(C_2H_5O_2)$; bromo-diethylin of glycerine, $(C_2H_5)_2Br(C_2H_5O_2)$. Preparation of dichlorhydrine. On glyceric acid-ether, $(C_2H_5O)(HO)(C_2H_5O)$; on glycolic acid diethyl-ether.

Brom-Benzo-Nitrile.—C. Engler.—This essay treats on—Brombenzoic acid ether, $C_6H_5Br.CO.O.C_2H_5$, a colourless, highly refractive fluid, boiling at 259°. Brom-benzamide, $C_6H_5Br.CO.NH_2$, a crystalline solid body, readily soluble in alcohol, difficultly so in cold water, and fusing at 150°. Brom-benzo-nitrile, $C_6H_5Br.CN$, a solid substance, exhibiting crystalline structure, fuses at 38°, boils at 225°, and is readily soluble in alcohol and ether.

Action of Sodium Amalgam upon Oxalic Ether.—S. Friedlander.—This paper is mainly a critical review of the statements made by A. Eghis (see *CHEMICAL NEWS*, vol. xxiv, p. 34) in reference to this subject, especially as regards the question of glycolinic and glycolic acid.

Researches made in the Chemical Laboratory of Lund (Sweden) University.—C. W. Blomstrand.—This memoir is divided into the following sections, of which only the titles are given, because, notwithstanding the intrinsic scientific value of this communication, the large number of formulae render useful abstraction impossible:—Derivatives from luteo- and roseo-cobaltic-iodo sulphate.—J. M. Krok. The sulphites of copper and silver and double salts thereof.—N. Svensson. On some of the sulpho-ethers of ethylene.—F. Ewerlöf.

Further Researches on the so-called Fore-Run (First Distillate) of the Spirit Distilleries.—A. Kekulé.—This memoir contains a detailed account of the labours of several chemists, among whom Dr. J. Weinzierl, Dr. Zincke, and others, on the constituents of the fore-run, especially in the case of the distillation of the fermented beet-root molasses. It appears, from what is here communicated, that the aldehyde, paraldehyde, metaldehyde, and acetal found in the fore-run are due to the action of small quantities of nitric, hyponitric, and nitrous acids, which are formed during the fermentation in small quantity.

Oxidation of Ketones.—A. Popoff.—The author describes at length the mode of preparation of methyl-phenyl-ketone, boiling at 200° , and the mode of its oxidation. The result of that process is that benzoic and carbonic acids are formed—

Ethyl-phenyl-ketone, boiling at from 208° to 212° , soluble in water, and combinable with bisulphite of soda, yields, by oxidation, benzoic and acetic acids—

Researches on the Uric Acid Group.—M. Nencki.—This paper contains, in the first place, a discussion on the constitution of the uric acid, and on the probability of synthetically preparing uric acid from sulpho-urea. In this direction, the author has experimented by mixing together sulpho-urea along with alloxan and alcoholic solution of sulphurous acid, and exposing that mixture for five hours in a sealed tube to a temperature of 100° . The result is that sulphopseudo-uric acid is formed, which, after having been purified, was found to consist of $N_3C_4O_5SH_6$; it is formed according to the following formula:—

This body is insoluble in water and ammonia, difficultly soluble in hydrochloric, but more readily so in hydrobromic and sulphuric acids, from which solutions it is precipitated by water; also soluble in caustic alkali solutions. The removal of the sulphur from this substance did not succeed. The author treats at considerable length on the products of decomposition of this substance.

Naphthol Compounds.—J. Grabowski.—This paper is divided into the following sections:—Oxalic acid and naphthol; chloride of phthalic acid and naphthol; pyromellitic acid and naphthol.

Products of the Reduction of Silicic Acid Ether and some of its Derivatives.—A. Ladenburg.—This lengthy essay does not admit of useful abstraction.

Monochlor-Crotonic Acid.—C. Sarnow.—The acid alluded to has been prepared by the author by causing zinc-dust to act, along with water, upon trichlor-crotonic acid, allowed to flow drop by drop into the water containing the zinc. The aqueous solution of monochlor-crotonate of zinc thus obtained is readily decomposed by hydrochloric acid, and the monochlor-crotonic acid purified by re-crystallising it from hot water, wherein this acid is readily soluble, as is also the case with alcohol and ether. Monochlor-crotonic acid, $C_4H_5ClO_2$, fuses at 94° , boils at 206° , and acts, when in contact with the skin, as an epispastic. This paper further contains chapters on monochlor-crotonid ($C_4H_5ClO.Cl$), monochlor-crotonamid ($C_4H_5ClO.NH_2$).

The Betain of the Phosphorus Series.—A. H. Meyer.—This valuable scientific paper is not suited for abstraction, owing to the large number of formulae required.

Some of the Derivatives of Piperidine.—J. W. Brühl.—This memoir is divided into the following sections:—Introduction, containing a review of the labours of Cahours and Hofmann on this subject; action of ethen-bromide upon piperidine; action of ethen-bromide upon ethen-dipiperidyl-diamine.

Methylation of the Phenyl Group in Aniline.—Drs. A. W. Hofmann and C. A. Martius.—This very lengthy and exhaustive monograph, full of formulae, contains, besides a lengthy introduction, the following sections:—Dimethyl-aniline; dimethyl-toluidine; dimethyl-xylidine; dimethyl-cumidine; dimethyl-cymidine.

Nature of the Sea-Water along the Coast of Bohuslän (Sweden).—Prof. J. L. Ekman.—From this lengthy memoir we quote the most interesting point—viz., that, as regards the quantity of salt contained in the sea-water on the west coast of Sweden, there is greater difference than for any other now known sea. The coast alluded to is, on the one hand, watered by the North Sea, and on the other by the Baltic. In the more northerly part the water at the surface contains rather less than 2 per cent salt, at 60 feet depth 2.5 per cent, at 90 feet depth 3 per cent; in the more southerly portion the discrepancies are greater, but at 600 feet depth 3.5 per cent salt is met with. The average quantity of salt of the oceans is 3.44 per cent; while in the Atlantic, from the equator to from 55° to 60° N. latitude, the quantity of salt in the surface-water is 3.66 per cent, and at depths of from 500 to 10,000 feet 3.578.

Annalen der Physik und Chemie, von Poggendorff, No. 5, 1871.

The original papers and memoirs of this number relating to chemistry and allied sciences are the following:—

Apparatus for Determining the Resistance which Atmospheric Air Exerts against Moving Bodies.—K. II. Schellbach.—A memoir illustrated by engravings.

Third Instalment of the Essay on the Friction which Particles of Gases exert upon each other.—O. E. Meyer.—An algebraico-physical treatise.

On Fluorescence.—E. Lommel.—An optico-mathematical essay.

Researches on the Electrophor.—W. von Bezold.—This lengthy memoir, illustrated by engravings, is, as regards its contents, strictly an algebraico-physical paper.

Description of a New Thermo-Galvanic Battery of Great Force.—Dr. A. von Waltenhofen.—Illustrated by engravings essentially required for the proper understanding of this apparatus.

Leidenfrost's Phenomenon.—R. Colley.

Experimental Proof of the Existence of Air in Water.—A. Andersohn.—The description of a complicated contrivance for experimentally proving a fact which is readily exhibited by the aid of an air-pump.

Stereoscopic Phenomenon produced by Dispersion.—F. Kohlrausch.—Illustrated by diagrams.

Simple means for Increasing the Deviation or Dispersion of a Ray of Light.—F. Kohlrausch.

Appendix to a Paper published in a former volume of this periodical, "On the Abnormal Dispersion Exhibited by Bodies Coloured on the Surface."—A. Kundt.

Melting of Lead Shot when Fired against an Iron Target.—E. Hagenbach.—After referring to a former paper on this subject, the author mainly states that Dr. A. Socin had exhibited to him balls extracted from wounds caused in the late war, some of which balls exhibited signs of fusion, thereby leading to the inference that, on the impact of the balls with bones, a great deal of heat is generated.

Observations on Thomson's Experiments on the Specific Heat of Aqueous Solutions.—A. Willner.

No. 6, 1871.

This number contains the following original papers relating to chemistry and allied sciences:—

Purity of the Surface of Films of Albumen and Tannin for Photographic Use.—C. Schultz-Sellack.

Studies on the Colouration of the so-called Smoky Quartz.—Dr. A. Forster.—An optico-crystallographical essay; but the main result of chemical investigation leads to the inference that the smoky colour is due to the presence in the quartz of a substance containing organic nitrogen and carbon.

Priority of the Discovery of the Relation existing between the Second Chief Axiom of the Mechanical Theory of Heat and the Principle of Least Action.—L. Boltzmann.

Contribution to our knowledge on Chlorophyll and some of its Derivatives.—E. Gerland and N. W. P. Rauwenhoff.—This paper, a spectroscopic-chemical essay, is illustrated by a series of engravings.

On the Rebound of Elastic Bodies, and the Determination of the Time Elapsing between each Rebound.—H. Schneebeli.

Refraction of Light Exhibited by Fuchsine.—C. Christiansen.—Optico-physical essay illustrated by engravings.

Second Essay on Abnormal Dispersion.—A. Kundt.

Improved Excitation Method for Electrical Machinea.—W. Musaeus.

Newly Improved Holtz's Machine Fitted with Double Discs turning in opposite directions, whereby twice as much Electricity can be Generated.—W. Musaeus.—The contents of these two papers, however interesting in a scientific point of view, do not admit of any useful abstraction.

Earthquake of Cosenza, October 4th, 1871.—G. vom Rath.—This essay contains the detailed description of everything which bears, in a geographico-physical and geological aspect, on this catastrophe, which destroyed a portion of Calabria (Sicily).

Chromate of Chrom-Oxychloride.—E. Zettnow.—The author describes at great length the mode of preparation of three specimens, compounds obtained by the action of strong sulphuric acid upon chlorochromate of potassa. The samples designated A and B are compounds the formula of which is $Cr_2Cl_2O + 4CrO_3$; in 100 parts—chromic acid, 60.42; chlorine, 21.43; chromium, 15.71; oxygen, 2.42. The sample designated C has the formula $Cr_2Cl_{18}O_{13} + 22CrO_3$; in 100 parts—chromic acid, 55.83; chlorine, 27.05; chromium, 15.85; oxygen, 1.22.

La Revue des Scientifique de la France et de l'Etranger,
August 19, 1871.

This number does not contain any original papers relating to chemistry, but contains the continuation and end of the very interesting lecture on the—

Influence of Heat upon Animals.—Dr. C. Bernard.

August 26, 1871.

This number does not contain any original papers bearing upon chemistry, but we meet here with a very excellent series of lectures on—

Respiration and the Renewal of Air in the Lungs.—Dr. Gréhant.—Illustrated by woodcuts.

September 2, 1871.

This number does not contain any original papers relating to chemistry or allied sciences.

Bureau Scientifique Central Néerlandais à Harlem, August 15, 1871.

Under this title, Dr. E. H. von Baumbauer has sent us a circular, the contents of which agree essentially with what has been already communicated to our readers on this subject (see *CHEMICAL NEWS*, vol. xxiv., p. 97). We only add here that Messrs. Williams and Norgate, of Ileneietta Street, Covent Garden, London, have been appointed as agents for the Bureau, which, as regards the United Kingdom, is in communication with all the most important of the scientific institutions and societies existing therein.

Le Moniteur des Produits Chimiques pour l'Industrie, les Sciences et les Arts et du Matériel de ces Industries Publié par une Société de Chimistes et d'Industriels, August 25, 1871.

In addition to several papers of economico-political and politico-industrial importance, this number contains the following original matter relating to chemistry:—

Pigments and Dyes known to and used by the Ancients.—E. Rousset.—The first portion of an essay on this subject. From the contents it appears that the author's primary object is to prove that the ancients were not so ignorant in industrial matters as is commonly supposed to be the case. Among the white pigments, they were acquainted with white-lead, which, according to Pliny, was prepared especially at Rhodes. As black pigments, various kinds of charcoal and soot were used by the Ancients, the same as nowadays; while they dyed animal skins black with nutgalls and sulphate of iron. By their acquaintance with the use of various kinds of ochre, and by mixing these, either with each other in various proportions, or with black pigments, brown pigments of various shades were obtained. Under the name of Alexandria blue, the Ancients (the author includes in that term the Ancient Egyptians, as well as Greeks and Romans) largely used and prepared a pigment containing oxide of copper, and they also were acquainted with a pigment containing cobalt; while indigo was not unknown to them, but not used for dyeing, their blue-dyed fabrics being obtained by the use of pastel-wood, *Isatis tinctoria*.

Improved Process of Soda Manufacture.—M. Swager.—By the joint aid of highly superheated steam and red-heat, the author decomposes the double chloride of aluminium and sodium, previously fused. The result is the formation of aluminate of soda and hydrochloric acid; the latter is condensed, the former, treated with carbonic acid, yields carbonate of soda and alumina.

Biography.—E. Rousset.—Under this heading the author here publishes another instalment of the life and labours of the late M. Payen.

Les Mondes, August 24, 1871.

This number contains the following original matter relating to chemistry and allied sciences:—

Use of a Screw Propeller fitted to Sailing Vessels.—E. Martin.—The author proposes to fit sailing ships with a screw propeller, to be act into motion by the movement of the ship while sailing, the object being to employ the mechanical power thus obtained for the purpose more especially of imparting movement to a magneto-electrical apparatus, with the view of giving to sailing vessels the advantage of electro-magnetic light on deck at nights, instead of the use of oil lamps now applied, for indicating the ship's course and presence to other vessels.

Elasticity of Caoutchouc.—E. Villari.—An algebraico-physical essay on the elasticity by stretching, and on the change of volume of caoutchouc.

Formation of a New Volcano in Sicily.—Rev. F. Moigno.—The author states that, on a mountain situated near Bivona (district of Girgenti), a crater has been opened.

Very Hard Cement.—Rev. F. Moigno.—Some repairs being required to the stone steps leading to a garden, the mason used Portland cement mixed with finely-divided cast- and wrought-iron filings and broken-up borings, instead of with sand. The result has been that the mass has become so hard as not to admit of being broken either with hammer or pickaxe.

Discovery of Coals in Norway.—Rev. F. Moigno.—In the island of Andø, off the coast of the province of Nordland, borings have been executed which have led to the discovery of seven seams of coal, varying in thickness from 0'06 to 0'50 metre.

NOTES AND QUERIES.

Lute for Nitric Acid—Test for Nitric Acid.—Can any of your readers inform me what is the best and cheapest lute for use in the manufacture of nitric acid? I have used plaster of paris, but do not find it to answer very well, and think there must be a better luting material in general use. What is the best and simplest tests for any nitrous compounds in sulphuric acid? Aniline and sulphate of aniline have already been suggested, but are these found to be the most exact in their test? What is the cheapest method of destroying both colour and smell in palm oils on a large or manufacturing scale?—CHEMIST.

Logwood Test for Alum.—(Reply to B. F. Munn.)—This test was first proposed by Dr. Horsy v. of Cheltenham, and has been thoroughly tried by Dr. R. Carter Muffat, who came to the conclusion that the best method of applying this test is as follows:—120 grms. of chips of logwood are digested in 8 ozs. of methylated spirits for eighteen hours, then filtered. This solution, when brought into contact with bread or flour free from alum, produced a pale yellow or straw colour, but a dark red when alum is present. The process is, therefore, simply to apply, to bread or flour suspected to contain alum, a portion of the alcoholic solution of logwood prepared as mentioned.

TO CORRESPONDENTS.

. We cordially thank those gentlemen who so kindly acceded to our request, in sending us the necessary information respecting the Chemical and Medical Schools for our Students' Number.

T. W.—You will find full particulars about Zeidellite in an English edition of Wagner's "Chemical Technology," which will shortly be published by Messrs. J. and A. Churchill.

R. W.—The pamphlet never arrived; we shall be glad to receive one. A. E. Tucker.—Your object is unattainable.

J. W. Taylor.—We have often quoted titles of books on the subject. Consult the Index to the *CHEMICAL NEWS*, or our "Answers to Correspondents."

BOOKS RECEIVED.

Annual Report of the City of New York for the years 1869 and 1870. Annual Report of the Board of Regents of the Smithsonian Institution for 1869. Washington.

New Remedies, a Quarterly Retrospect of Therapeutics, Pharmacy and allied subjects. Edited by Horatio C. Wood, jun., M.D. New York: William Wood and Co.

Lecture on the Analysis of Coal-Gas. By Henry Letheby, M.B., M.A., &c. Delivered before the British Association of Gas-Managers. London: William B. King.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871–1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of "PRACTICAL BOTANY" will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c. All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

THE CHEMICAL NEWS.

VOL. XXIV. No. 617.

ANALYSIS OF PITTICITE, FROM REDRUTH, CORNWALL.

By Professor A. H. CHURCH, M.A.

CAREFULLY selected homogeneous portions of a fine specimen of this mineral from Cornwall were submitted to analysis, after having remained a year or more in my cabinet. They evidently still contained a considerable amount of hygroscopic water.

Water lost at 100° C.	8.76
„ lost at 175°	7.53
„ retained at 175°	8.63
Ferric oxide	32.54
Arsenic pentoxide	33.99
Phosphorus pentoxide	1.27
Sulphur trioxide	7.28

100.00

Regarding the water lost at 100° as non-essential or accidental, we may re-calculate the above numbers as follows:—

Water	17.71
Ferric oxide	35.67
Arsenic pentoxide	37.25
Phosphorus pentoxide	1.39
Sulphur trioxide	7.98

100.00

I fear that these numbers throw no fresh light upon the constitution of this very variable mineral, and that no satisfactory formula can be deduced from them. Yet there can be little question but that they belong to pitticite, a species which has not, I believe, hitherto been definitely ascertained to be British. One peculiarity of the Cornish specimens consists in the high proportion of arsenic pentoxide which they contain, a proportion which is greater than that in this mineral as derived from any other recorded locality. But, on the other hand, the Cornish pitticite shows a smaller quantity of ferric oxide than the other analysed specimens. It does not appear that phosphorus pentoxide has been previously detected in this mineral. I ought to add that the Cornish mineral was straw to ochre-yellow in colour, subreniform and massive in form, and in great part opaque. The softest, palest, and most homogeneous portions were selected in preparing the sample for analysis. It is not improbable that the darker and less opaque portions would have shown a higher percentage of iron.

CONTRIBUTIONS TO THE HISTORY OF THE PHOSPHORUS CHLORIDES.*

By T. E. THORPE, Ph.D., F.R.S.E.

1. On the Reduction of Phosphoryl Trichloride.

In his first memoir on vanadium, Dr. Roscoe described a series of oxychlorides obtained from vanadyl trichloride by the action of reducing agents. When the vapour of vanadyl trichloride is passed, together with hydrogen, through a heated tube, a bright grass-green crystalline sublimate of vanadyl dichloride, VOCl_2 , is produced in

the anterior portion of the tube; afterwards, a layer of vanadyl monochloride, VOCl , is deposited as an exceedingly light flocculent brown powder; whilst, at the extreme end of the tube, beautiful bronze-coloured plates of the divanadyl monochloride, $\text{V}_2\text{O}_2\text{Cl}_4$, are formed, which have the appearance of mosaic gold. In this memoir, Dr. Roscoe clearly pointed out the intimate analogy which exists between the compounds of vanadium and those of phosphorus, arsenic, antimony, and nitrogen, and, in his subsequent researches on this subject, he has so far elaborated this view of its chemical relationship, that there is no longer room to doubt that vanadium is virtually a member of the trivalent group of elements.

It must be confessed, however, that the triatomic nature of vanadium is not very apparent in the oxychlorides derived from the vanadyl trichloride if the simplest formulæ derived from their analysis be retained; but, if these formulæ be doubled, the difficulty at once vanishes. The supposition, that these oxychlorides possess a greater molecular weight than the vanadyl trichloride, may derive some support from the fact of the change of physical state which accompanies their formation, the lower oxychlorides being all solid. Beyond this, I am not aware that any fact is known to establish such an assumption, unless it be the coincidence between the atomic volume of the vanadyl trichloride and that of the vanadyl dichloride with the formula doubled—

	Specific gravity.	Atomic weight.	Atomic volume.
VOCl_3 . .	1.83	173.8	95.0
$\text{V}_2\text{O}_2\text{Cl}_4$. .	2.88	276.6	96.0

According to this view, the formulæ of these oxychlorides and their relation to the vanadyl trichloride would be thus graphically represented—

And, just as the $\text{V}_2\text{O}_2\text{Cl}_4$ is formed by the juxtaposition of 2 molecules of VOCl_3 minus 2 atoms of chlorine, so, in like manner, the $\text{V}_4\text{O}_4\text{Cl}_2$ may be represented as derived from 2 molecules of $\text{V}_2\text{O}_2\text{Cl}_2$ minus 2 atoms of chlorine, thus—

So far as I am aware, there is nothing to disprove such a method of representation; it has, at least, the merit of preserving the triatomic nature of vanadium in these compounds, and shows in a simple manner their relation to the vanadyl trichloride.

* Read before the British Association, Edinburgh Meeting, Section B.

Assuming, then, that the triatomic nature of vanadium is established, analogy points to the existence of other oxychlorides among the trivalent group than those at present known to us. To fulfil the relationship we ought to have VOCl_3 , $\text{T}_2\text{O}_2\text{Cl}_4$, $\text{T}_2\text{O}_2\text{Cl}_2$, and $\text{T}_4\text{O}_4\text{Cl}_2$, where T represents a member of the triatomic group of elements. The following table represents these analogies so far as they are complete:—

VOCl_3	—	POCl_3	—	SbSCl_3
$\text{V}_2\text{O}_2\text{Cl}_4$	$\text{N}_2\text{O}_2\text{Cl}_4$	—	—	—
$\text{V}_2\text{O}_2\text{Cl}_2$	$\text{N}_2\text{O}_2\text{Cl}_2$	—	$\text{As}_2\text{O}_2\text{Cl}_2^*$	$\text{Sb}_2\text{O}_2\text{Cl}_2^\dagger$
$\text{V}_4\text{O}_4\text{Cl}_2$	—	—	—	—

The $\text{V}_2\text{O}_2\text{Cl}_4$ was also prepared by Roscoe by heating VOCl_3 in a sealed tube with fragments of metallic zinc to a temperature above the boiling-point of mercury; in this way the compound was obtained in quantity, and it was easily freed from a small quantity of adhering VOCl_3 by heating to 130°C . in a current of dry carbon dioxide. I have attempted to repeat this reaction with phosphoryl trichloride. A quantity of the pure liquid was sealed up together with zinc filings in a tube, and heated to about 400° . The zinc was slowly acted upon, and a transparent glassy mass was formed at the bottom of the tube; no evolution of gas occurred on opening the tube. The small quantity of liquid remaining was submitted to distillation; it commenced to boil at about 80° , and the thermometer gradually rose to 105° , by which time the whole of the liquid had passed over. This behaviour appeared to indicate the presence of phosphorus trichloride, PCl_3 , and a few drops of the liquid, decomposed by water, yielded the reactions of phosphorous acid. The quantity was too small to admit of fractional distillation, even if the perfect separation of the two liquids had been practicable by this method; accordingly, three portions of the distillate were weighed out for determination of the chlorine, total phosphorus, and amount of phosphorus yielding phosphoric acid on decomposition with water.

1. *Determination of Chlorine.*—The weighed quantity of liquid was decomposed by water in a stoppered bottle, a quantity of nitric acid added, and the chlorine precipitated with silver nitrate.

0.6032 grm. gave 1.7764 AgCl and 0.0075 Ag.

Cl found.	Calculated	
	For POCl_3 .	For PCl_5 .
73.21 per cent	69.36	77.43

2. *Determination of Total Phosphorus.*—The mixed chlorides were decomposed by water in the manner above described, nitric acid added, and the liquid concentrated. The fluid was then made strongly alkaline by ammonia, and the phosphorus precipitated as the magnesium ammonium compound.

1.3343 grms. gave 1.0077 magnesium pyrophosphate, or 21.09 per cent P.

3. *Determination of the Phosphorus existing as Phosphoryl Chloride yielding Phosphoric Acid on Decomposition with Water.*—The bulb containing the weighed portion was broken under water, and ammonia and "magnesia-mixture" immediately added.

1.3965 grms. gave 0.5174 magnesium pyrophosphate, or 10.58 per cent P; equivalent to 52.35 per cent POCl_3 .

These numbers almost exactly correspond to a mixture containing equivalent quantities of POCl_3 and PCl_3 ; such a mixture would give—

	Found.
Cl	73.17
Total P	21.32
P giving PO_4H_3 ..	10.66
	10.58

The vitreous mass remaining in the tube fused on gently heating, and was decomposed; it was probably a combination of one of the above chlorides with zinc chloride,

* Wallace's chlorarsenic acid.
† Schaeffer.

possibly the $\text{ZnCl}_2 + \text{POCl}_3$ already described by Casselmann, mixed with zinc oxide or zinc oxychloride.

The action of zinc at a high temperature on phosphoryl trichloride is therefore sensibly different from the action of this metal on the corresponding vanadium compound; in the former case, the reaction is attended with abstraction of oxygen; in the latter, with abstraction of chlorine.

II. Note on the Preparation of Phosphorus Sulphochloride.

This compound was first prepared by Serullas, who obtained it by the action of sulphuretted hydrogen upon the pentachloride of phosphorus—

This reaction, however, affords only an impure product. Baudrimont states that this compound is more easily prepared by the action of pentachloride of phosphorus on antimony trisulphide—

It has long been known that phosphoryl trichloride may be easily obtained in a state of complete purity, by the action of pentachloride of phosphorus on phosphoric anhydride—

It occurred to me to try whether the sulphochloride might not be produced by the analogous reaction with phosphorus pentasulphide—

The materials, mixed in this proportion, were heated in a sealed tube to about 150° ; in a few minutes, combination was quickly effected, and the entire contents of the tube were transformed into colourless phosphorus sulphochloride—a mobile liquid, boiling constantly at 126° at 770 m.m. Bar. Its vapour is extremely irritating, but when diluted with air it has an aromatic odour, reminding one of that of the raspberry.

ON RECENT INVESTIGATIONS AND APPLICATIONS OF EXPLOSIVE AGENTS.*

By F. A. ABEL, F.R.S., Treas. C.S.

(Continued from p. 129).

THE meeting of the British Association in 1862 marks the period when gun-cotton, which fell into disfavour in England and France within two years of its discovery by Schönbein in 1846, again attracted public attention in this country. A committee was appointed at the Cambridge meeting to report on the system of manufacturing and applying gun-cotton, which had been elaborated in Austria by Baron von Lenk; and, early in the year following Her Majesty's Government received from that of Austria a confidential communication of the full details respecting von Lenk's improvements. I was at once called upon, in the spring of 1863, to investigate practically and scientifically the merits of the several modifications which had been imported into the original process of manufacture, as laid down by Schönbein; and, early in the year following, a committee was appointed by the Secretary of State for War, under the presidency of Sir Edward Sabine (and including several members of the British Association Committee), with instructions "to investigate the properties of gun-cotton as a substitute for gunpowder." The continuance of the chemical and manufacturing portion of these investigations being left in my hands, as a member of that committee, the results arrived at with regard to the production and composition of gun-cotton, the causes to which the uncertain stability hitherto exhibited by it were to be ascribed, and the extent to which Von Lenk's improvements had removed or reduced these, were communicated by me from time to time to the Committee and the Royal Society. Some very searching experiments were made upon a considerable scale, for the Com-

* A Lecture delivered to the Members of the British Association at Edinburgh, August, 1871.

mittee, with gun-cotton manufactured according to Von Lenk's process, at Waltham Abbey, with a view to ascertain whether the requisite confidence could be placed in its keeping qualities, and the results were so far satisfactory, that the Committee, in the Report which they submitted in 1863, were enabled to state that strong evidence had been afforded of the stability of the material when properly manufactured; though they considered that further experience was required to determine this important point with sufficient certainty to justify a general adoption of gun-cotton for military service. The various samples of gun-cotton upon which the Committee based their conclusions in 1863 have been preserved to the present day, under the same conditions; recent inspection has shown them to be quite unaltered. A further experience of more than three years has, therefore, been acquired, favourable to the stability of the material, most of which was manufactured eight and seven years ago. With regard to the methods of preparing gun-cotton for mining purposes, and for artillery and small-arms, devised by Von Lenk, which have been described in detail to the British Association at former meetings, the results arrived at by the Committee did not sufficiently bear out the expectations which at first were entertained of the practical value of those methods, to warrant any decisive conclusion of a favourable nature being arrived at; and it was obvious that much remained to be done to obtain proper control over the explosive power of gun-cotton, and to render it really susceptible of being safely and beneficially substituted for gunpowder.

In examining the results obtained when gun-cotton was fired under pressure (*i.e.* in confined spaces), and observing the very limited and uncertain extent to which the explosive violence of the material was subjected to regulation, under those circumstances, by the methods of twisting and winding, and other expedients employed by Von Lenk to give compactness to a charge of the fibrous material, I was led to believe that there would be much greater prospect of attaining the desired results if gun-cotton could be converted into a form readily susceptible of treatment by compression, so as to furnish perfectly homogeneous masses of required form and density,—resembling gunpowder, in fact, in their physical character. This object was attained by submitting the gun-cotton fibre to the pulping process applied in the preparations of rags and fibres for paper-making, and afterwards converting the pulp into sheets or moulded masses, to which perfect compactness and a high density could be given without difficulty, by means of well-known mechanical appliances.

This modification of the method of preparing gun-cotton, when applied to the preparation not only of mining charges, but also of cartridges for small-arms and for artillery of small calibre, soon furnished decisive and very promising results. The experiments hitherto instituted with compressed gun-cotton in small arms and artillery have been only of preliminary nature, as already stated; but the substitution of charges of compressed gun-cotton for blasting and mining operations, in place of the gun-cotton rope hitherto employed, was not only at once productive of greatly improved results on account of the considerable reduction effected in the size of the charges of a given weight, but also imparted to the material a character of safety (in its storage, and all manipulations with it) which it did not hitherto possess, as the masses of compressed gun-cotton cannot be made to explode by accidental ignition unless they are very strongly confined. The advantages resulting from the application of the pulping process to gun-cotton were, however, not limited to the improvements effected in its efficiency as an explosive agent, but extended, with a degree of importance scarcely at first anticipated, to the properties of the material, specially in regard to stability, and to its manufacture, which was speedily quite revolutionised thereby. Thus, instead of the raw cotton of high quality and long staple, which it had been necessary to use in carrying out the Austrian

system, any description of cotton could be employed, and the waste cuttings from spinning-machines (such as are used for cleaning machinery) proved to be as suitable as cotton in any other form.

The purification of the raw cotton from seed and from other matters foreign to cellulose, which are contained in the hollow fibres, constituted a most important preliminary operation in the Austrian process. Even by a searching treatment with alkali, and careful washing, these impurities were never thoroughly removed; and the products of somewhat indefinite and comparatively unstable nature, produced by the action of the acids upon these traces of organic impurities, and occasionally remaining in the finished gun-cotton, were clearly shown in the investigations which I carried out on the stability of this substance, to be the starting-point in any change which gun-cotton might sustain by long exposure to elevated temperatures. The cotton-waste now used in making gun-cotton has undergone so thorough a purification by the various manufacturing processes through which it has passed, that, while no further preliminary purification is requisite, the finished gun-cotton obtained from it is practically free from the impurities just referred to.

The cotton having been treated with the mixed nitric and sulphuric acids, and the greater portion of the acids afterwards separated, the subsequent processes of purification and preparation differ entirely from those pursued in Von Lenk's system. The purifying processes prescribed by the latter, and demonstrated experimentally to be absolutely essential in dealing with gun-cotton in the form of fibre, consisted in very long-continued washing (extending over several weeks) in running water, and subsequent treatment with alkali. The capillarity of the long fibres constituted the great obstacle to rapid purification, the displacement of the acid from the interior of these being obviously a very slow operation. In the present system of manufacture the gun-cotton is rinsed two or three times in a large volume of water, the latter being extracted as completely as possible between each rinsing by means of centrifugal apparatus; it is then transferred to a rag-engine of the kind ordinarily used in producing pulp for paper-making. Here it is not only reduced to the state of fine division necessary for its subsequent conversion into homogeneous compressed masses, but it also undergoes at the same time a most searching purification, which is continued in a still more complete manner in the next operation, the pulp being transferred to what is technically called a poaching-engine, where it is beaten about so as to remain uniformly suspended in a large volume of warm water, continuously renewed, and rendered slightly alkaline at the close of the operation. This washing is carried on uninterruptedly until samples of the material under treatment have satisfactorily sustained a very severe heat-test, and generally lasts about forty-eight hours. At least 10 cwt. of gun-cotton are washed at one time in the poaching-machine; in this way an exceedingly intimate mixture of the products of many dipping operations is obtained, and any fluctuations in the composition of the gun-cotton are thus made to counterbalance each other, much greater uniformity in the explosive power of the product being obviously secured than was previously attainable. When the gun-cotton pulp is completely purified it is converted into compact masses of the desired forms and density by a preliminary moulding process, and subsequent application of hydraulic pressure ranging from 4 to 6 tons upon the square inch. During the whole of these manufacturing operations the gun-cotton is wet, and therefore absolutely unflammable. Even when it leaves the presses it still contains about 20 per cent. of water, and is so perfectly safe in this condition that slabs of it may be cut up by means of circular or band saws, revolving very rapidly, and holes drilled in it by drilling machines, or even by means of a red-hot iron. In this damp and incombustible condition the compressed gun-cotton may be stored in water-tight cases for any length of time; the final drying of the masses is carried on ver

rapidly and safely upon hot plates, which are freely open to the air at the sides.

Numerous experiments, on a considerable scale, have been made with a view to thoroughly test the safety of compressed gun-cotton. Deal boxes, filled with the material in the ordinary way in which it is stored, and securely closed, have been arranged in piles, and the contents of a box in the centre of the pile have been ignited by means of a fuse. In another experiment one of the inner boxes of a pile has been surrounded by highly combustible material, and the latter inflamed, so as to envelope the box in fire. In all instances the contents of the one box have ultimately burnt, but without even shattering the latter, and the large volume of flame produced for a few moments sometimes penetrated to the interior of another box in the heap, causing its contents to inflame in like manner but in no instance was an explosion produced. Those boxes the contents of which were intact were removed from the pile without incurring any danger, although the inflamed boxes were still burning. Closed boxes, filled with compressed gun-cotton, have been fired at with a Martini-Henry rifle from a distance of 100 yards; in some instances the box and contents were perforated by the bullet without igniting the gun-cotton; in other instances the contents were inflamed, but no explosion occurred. Numerous other practical proofs have been obtained of the safety of compressed gun-cotton as compared with gunpowder, and with gun-cotton in the comparatively loose and open condition.

When the Austrian improvements in the preparation of gun-cotton were communicated to the British Association in 1864, great stress was laid upon the fact that the proper development of its explosive force could only be effected by confining the material in receptacles of considerable strength, as in shells, in firmly tamped boreholes, or very strong cases of wood and metal. In attempts made by our Royal Engineers in the autumn of 1863 to apply gun-cotton to the demolition of the works at Corfu, the operations failed, in the majority of instances, to furnish any satisfactory results, evidently on account of deficiency in strength of the cases, specially constructed for this purpose, in which the charges of gun-cotton were supplied by the Austrian Government. These, and other unfavourable results, warranted the conclusion that gun-cotton could not be advantageously applied as a substitute for gunpowder in connection with military operations of mining and demolition which it is desirable to be able to accomplish hastily, and for which consequently few men and appliances, and little preparation, should be needed.

(To be continued).

ON THE ACTION OF HEAT ON PROTOPLASMIC LIFE DRIED ON IN COTTON FABRICS.

By F. CRACE CALVERT, F.R.S.

THE papers which I have previously published on the action of heat on animalcule life have being almost entirely of a purely scientific character, I propose in this to give a series of experiments which have a direct bearing on the question of the disinfection of fabrics and wearing apparel by the application of heated stoves, with the object of destroying contagion or animalcule life.

To carry out these views, a piece of ordinary grey calico was treated chemically, and washed until free from any sizing material, and dried; this prepared cloth was then steeped in a solution of putrid albumen containing abundance of animalcule life, wrung out, and dried at the natural temperature; it was then cut into small pieces, 5 centimetres square. Each of the pieces was then folded in two, rolled up, and introduced into a small strong glass tube of 6 centimetres in length

and 9 millimetres in diameter; each tube was then hermetically sealed at the blowpipe.

These specimens of calico were prepared on the 8th of August, and on the 9th thirty-five small pieces were sealed in tubes. On the 10th, five of the tubes were set aside, and the remaining thirty were placed in an oil-bath and gradually heated up to 100° F., and kept at that temperature for half an hour. Five of the tubes were then taken out, and the temperature raised successively to 200°, 300°, 400°, 500°, and 600° F., kept at each temperature half an hour—five tubes being taken out at the end of each half-hour, or at each of the above points of temperature.

On the following day, one of the tubes which had been heated at each determined temperature was opened, the cloth moistened with water, and a quarter of an hour afterwards examined under the microscope, giving the results specified on Table I.

On the 14th of August, one of the small tubes from each series was broken, and the heated cloth introduced into seven tubes, each containing 400 grains of pure distilled water free from life, and left for three days to ascertain if the life which had resisted 200° and 300° F. was still capable of reproduction, and if the germs, as well as the animalcule, had been destroyed by a temperature of 400°, 500°, and 600°.

A second series was made by introducing similar pieces of cloth, which had been also heated to the different temperatures, into tubes containing an albumen solution, made by mixing one part of white of egg with four of absolutely pure distilled water free from any trace of life, and these set aside for the same length of time to corroborate the above results.

The different fluids from both series were then microscopically examined on the 17th inst., and Tables II. and III. show the result.

From an examination of Table I., it will be seen that life was *not* destroyed in the fabric at a temperature of 300° F., whilst it is destroyed at 400°, and that these results coincide with those obtained when microscopic life were submitted to heat in the fluids in which they had generated, but differ from those observed in the experiments described in my last paper where a fluid full of microscopic life was placed on slips of glass dried carefully, either at natural temperatures or in an air-bath at 212° previously to being heated in the oil-bath at higher temperatures—and no doubt it will have been noticed that life disappeared after 300° in the former, whilst it was only destroyed after 400° in the latter; these results are no doubt due to the albuminous nature of the protoplasmic life existing under these circumstances. These facts are in accordance with results obtained by my learned master, M. Chevreul, forty years since,—namely, that it requires a much higher temperature to render albumen insoluble when once deprived of its water than when it is in its natural state,—and all chemists know that the coagulating-point of an albuminous solution bears a certain ratio to its point of concentration. The only explanation I can offer for the destruction of life at 300° in dried calico, is that the fabric (having been, as will be seen further on, softened at 300°) proves that it has undergone a decomposition, and, therefore, that part of its elements have united together to form water, which would become high-pressure steam at the temperature at which I operated, and, to use a common expression, cook the albumen.

It will also be remarked that the amount of life in the cloth heated to 300° is similar to that on the plates of glass—viz., that in both instances it is much more abundant than when such animalcules were heated in the fluids in which they had generated, which illustrates the fact that the greater the amount of fluid in which animal life exists, or the larger the proportion in which it exists in the animal itself, the lower is the temperature at which life is destroyed.

As it was interesting to know what changes the calico had undergone at the various temperatures above cited,

TABLE I.—Examination of the fabrics after having been heated as follows:—

Water used for Experiment.	Cloth. Not heated.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No vibrios nor bacteria.	2. A considerable quantity of vibrios are present moving to and fro. No swimming vibrios are present.	3. About the same quantity of life is present here as in 2, and with about the same amount of vitality.	4. A little less amount of vibrios is present here than in 2 or 3, but a large quantity is still present, and they possess about the same vitality as 2 or 3.	5. Considerably less life here than in 4, but several distinct vibrios are present under each field moving to and fro.	6. No life.	7. No life.	8. No life.

TABLE II.—*Water Series*.—Examinations of the fluids in which some of the heated fabrics had been introduced. This series commenced on August 14, 1871; examined microscopically on August 17.

Water alone for comparison.	Cloth. Not heated.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No vibrios nor bacteria.	2. The whole bottom part of each of the fields of the microscope is covered with long, ordinary, and small-sized bacteria. Three or four ordinary, long, and small vibrios are swimming about under each field.	3. Thirty to forty long bacteria, and three or four long swimming vibrios are present under each field.	4. Forty or fifty long, ordinary, and small bacteria are present under some of the fields, and very large shoals of these bacteria under others. One or two long vibrios are swimming about under each field.	5. The bottom parts of each field is covered with ordinary, long, and small bacteria. And a considerable number of long vibrios are present throughout the drop.	6. No bacteria, and no vibrios present.	7. No bacteria, and no vibrios present.	8. No bacteria, and no vibrios present.

TABLE III.—*Albumen Series*.—Examination of the albuminous solutions in which had been introduced heated fabrics. Commenced on August 14, 1871; examined on August 17.

Albumen solution alone for comparison.	Cloth. Not heated.	Heated to 100° F.	Heated to 200° F.	Heated to 300° F.	Heated to 400° F.	Heated to 500° F.	Heated to 600° F.
1. No vibrios present.	2. Twenty to thirty ordinary vibrios and microzoma, and a small number of long and very long vibrios are present, swimming about in all directions under each field.	3. Nine or ten long and very long swimming vibrios, and four or five long vibrios, merely moving to and fro under each field.	4. About the same amount and kind of life is present here as was observed in 3, or that heated to 100° F.	5. Four or five long and very long swimming vibrios and one or two small lots of vibrios joined together.	6. No vibrio present.	7. No vibrio present.	8. No vibrio present.

one of each of the small tubes which had been heated to the different temperatures was broken, and its contents carefully examined. The piece of fabric which had not been heated at all and those heated to 100° and 200° F. were quite sound; whilst that heated to 300° was of a slightly brown colour, much injured, and for practical purposes completely spoiled. At 400° F. the cloth was very much charred, almost black, and crumbled easily into powder when rubbed between the fingers; the tubes contained a large volume of gases, owing to the decomposition of the cloth. At 500° F. the cloth had been completely carbonised, and the tube contained also much gas. At 600° F. the cloth was completely decomposed into charcoal, and various hydrocarbon gases generated.

The above results clearly show that germ life placed under the above circumstances is not completely destroyed at 300° F., whilst it is at 400° . These facts not only confirm my previous results, but demonstrate, at the same time, that the temperature which will not destroy germ life is quite sufficient to materially injure cotton fabric. From these carefully conducted experiments, I am led to the conclusion that no beneficial results can be obtained by the employment of public stoves as a means of destroying germ life and contagion.

ON THE

ESTIMATION OF SULPHUR BY BARIUM.

By NICHOLAS GLENDINNING and ALFRED EDGER,
Newcastle-on-Tyne.

OUR experience in the estimation of sulphur in pyrites by the gravimetric method has not led us to the same conclusion as that arrived at by Messrs. Teschemacher and Smith.

We have often had occasion to make duplicate determinations of sulphur in the same sample of pyrites, and the results have been such as to prove to our satisfaction that the method is capable of giving at least concordant results.

We are of opinion that Messrs. Teschemacher and Smith attribute too much of the differences between results obtained by this method to the solubility of sulphate of barytes in hydrochloric acid. The fact that sulphate of barytes is gradually deposited when the clear filtrate and washings are allowed to stand for some time, will admit of a different explanation than that offered by them, that "sulphate of barytes is noticeably soluble in hot and but moderately diluted hydrochloric acid." We attribute this to sulphate of iron, which is invariably carried down with the sulphate of barytes, and which appears on treatment with hydrochloric acid, after the precipitate has been freed from chloride of barium. That this is a correct interpretation may be proved by the following experiment. Oxidise about 50 grs. of pyrites, evaporate to dryness, add hydrochloric acid, and again evaporate to dryness; then take up with about 100 fluid grains of hydrochloric acid, add water and filter, and to the filtrate, at the boiling-point, add chloride of barium gradually and in excess; allow to stand for two or three hours, then filter and wash the precipitate of sulphate of barytes with hot water, until sulphuric acid fails to indicate barium in the washings; at this point treat the precipitate with hot, moderately dilute hydrochloric acid and filter; repeat this operation two or three times, then evaporate the acid washings to dryness, take up with a few drops of hydrochloric acid and water, filter to remove any trace of sulphate of barytes, and to the filtrate add chloride of barium, which will at once produce a precipitate of sulphate of barytes. In making this experiment care must be taken to use hydrochloric acid, which leaves no sulphuric acid on evaporation.

In the actual determination of sulphur, it is of great importance to obtain the precipitates as free as possible

from sulphate of iron, and more especially when they are to be treated with hydrochloric acid after ignition, otherwise a loss is unavoidable.

It is our experience that the longer the precipitated liquor is allowed to stand, the freer the sulphate of barytes is found to be from sulphate of iron.

We have found in many instances on treating ignited sulphate of barytes with hydrochloric acid, that small quantities of sulphuric acid might be detected in the washings, but when precipitates have been subjected to an intense heat for a considerable length of time, such will probably not be the case.

We have since the publication of Messrs. Teschemacher and Smith's paper made experiments on a sample of pyrites, the results of which we beg to lay before our readers after first describing the *modus operandi*, which is as follows:—

Four portions of pyrites, 25 grs. each, were oxidised by red fuming nitric acid, evaporated to dryness in a water-bath, re-dissolved by a little hydrochloric acid, and again evaporated to dryness, again re-dissolved in hydrochloric acid, water added and filtered; the filtrates, measuring about ten ounces each were then heated to about 180° F., and the sulphuric acid precipitated by gradual addition of chloride of barium. It sometimes occurs on heating the filtrates before precipitation, that they assume a deep reddish colour: we consider this an unfavourable condition of the solution, and we add a little hydrochloric acid, which restores the light amber colour.

The precipitated liquors were allowed to stand in a warm place for about eight hours, and then filtered. We intended to have examined the strong filtrates for sulphate of barytes, but were prevented by want of time; but we can say from previous experience that only traces would have been found.

The sulphate of barytes precipitates were washed repeatedly by decantation with small quantities of hydrochloric acid and boiling water, until the addition of a little strong hydrochloric acid to the precipitate failed to give a colouration indicative of the presence of iron. They were then transferred to the filters, and thoroughly washed with boiling water. The whole of the washings, after the addition of a little chloride of barium, were evaporated to dryness, and the quantities of sulphate of barytes obtained, amounting generally to about 0.5 grs., added to the original precipitates, three of which after ignition and weighing, were treated with about 500 grs. strong hydrochloric acid, and allowed to stand for twelve hours in a warm place; the small quantities of sulphate of barytes dissolved by the acid were recovered and added to their respective precipitates.

The following are the results:—

	Before treatment with HCl.		After treatment with HCl.	
	Grs. BaOSO ₃ .	Grs. S.	Grs. BaOSO ₃ .	Grs. S.
No. 1	= 83.12	= 11.415	83.08	= 11.411
" 2	= 83.18	= 11.423	83.12	= 11.415
" 3	= 83.30	= 11.440	83.23	= 11.430
" 4	= 83.23	= 11.430		

It will be seen from the above figures that the greatest loss on treating the precipitates with HCl amounts to only 0.07 grs. BaOSO₃, probably attributable to the precipitate having retained a small quantity of sulphate of iron. We think the above experiments are sufficient to prove that constant results and precipitates of reliable purity are obtainable by the gravimetric method.

We have not had an opportunity of experimenting on protosulphate of iron, but we are of opinion that the estimation of sulphuric acid in the oxidised substance presents a greater difficulty than is offered in the case of pyrites, inasmuch that the proportion of oxide of iron to the sulphuric acid is much greater in the case of protosulphate of iron than in that of oxidised pyrites.

We have shown that sulphate of iron is carried down with sulphate of barytes, and are of opinion that this

property, which offers the greatest drawback to the gravimetric method, will also affect the results obtained by the volumetric method recommended by Messrs. Teschemacher and Smith.

NOTES FROM THE INTERNATIONAL EXHIBITION OF 1871.

THE chemical contributions to the exhibition of this year are very few, but of the highest technical importance. And here arises a difficulty as to the order in which they shall be considered, the dispersion in various parts of the building precluding the following of the numbers of the catalogue; while it would be impossible to make an arrangement according to merit. It is perhaps the best plan to walk through the building, and observe which chemical products exhibited most attract the attention of the visitors. Entering the exhibition at the south-east gate, where most of the visitors arrive, and, being bent upon a scientific exploration, allowing but a few minutes to the seductive curiosities of the Indian Court, we pass by the collection of British and foreign paintings, the valuable Meyrick collection of armour, down and up the steps where the Whitworth ordnance stood when these galleries formed part of the South Kensington Museum, to the ground floor of the West Gallery, chiefly devoted to scientific invention. Bearing our object in mind, the case most eulogised by the visitors in the exclamation "Those beautiful colours," is that (7609) belonging jointly to Messrs. E. C. Nicholson and D. S. Price, in which are exhibited the coal-tar products, rosaniline-base, acetate of rosaniline, and chloride of rosaniline. Fourteen years ago, aniline-violet, or "mauve," the first colour from coal-tar, was prepared on a practical scale by Mr. W. H. Perkin; next, in 1859, followed aniline-red or magenta, and then a series of brilliant colours. The present exhibit is illustrative of the system of manufacturing the magenta dyes. In 1859, when Messrs. Verguin and Renard Frères first manufactured aniline-red by the action of tetrachloride of tin upon aniline, there was little idea of the extension of the industry that would ensue from the discovery of Messrs. Nicholson and Price that this colour is the salt of a colourless base, rosaniline. (7609) includes two blue dyes derived from aniline, exhibited by Mr. E. C. Nicholson on his own account; they were first prepared in 1862 and 1863, and both are of considerable technical importance. The first is known as "soluble blue," and is produced by the action of strong sulphuric acid upon Girard's blue, also a product of aniline. For wool it has little affinity, even with a mordant, consequently its use is limited to the dyeing of silk and feathers. It is the salt of a new acid, the constitution of which is as yet unknown; but it will probably prove to be a conjugate sulpho-acid, bearing a similar relation to Girard's dye as sulphindigotic acid does to indigo. The salts with the alkaline bases are very soluble in water, but with difficulty in alcohol; the aqueous solution, if neutral, has a light blue tint, nearly disappearing on the addition of an alkali. The blue colour is developed, but not precipitated, by acids. The export of this dye in the dry state to China and the East is very large, on account of the ease with which it may be applied, and the excellence of the result. Mr. Nicholson's second dye, known as "Nicholson's blue," or "fast blue," is intended for woollen fabrics, to which it is peculiarly suited by its property of dyeing in an alkaline solution, and to its entire insolubility when precipitated by a mineral acid. The process of dyeing with this colour is also due to Mr. Nicholson, and is extremely simple. The goods are first boiled in an alkaline bath, to which the quantity of dye required to produce the desired tint has been added; the whole of the dye in the bath is soon absorbed; the goods are then washed and passed into a bath of boiling

water, containing a small quantity of a mineral acid, in which the blue colour is developed. As the dye exists in solution in the first bath instead of in suspension, the fibres of the material are completely penetrated by it; and when the second bath is employed, precipitation of the blue colour instantly takes place among the fibres; thus a fast colour is obtained, slightly affected, however, by washing with soap.

Messrs. Perkin and Sons have a most interesting case (7516) illustrating the conversion of anthracene into alizarine. The series includes the two extremes, crude anthracene and the pure colouring matter; and also specimens of fabrics dyed and printed with artificial alizarine. Messrs. Southwall and Briggs (7550) exhibit anthracene purified by pressure and sublimation according to Mr. Wavey's process, as well as the several stages of conversion into alizarine.

Allied to aniline, as a constituent of coal-tar, is phenol, or carbolic acid, first manufactured in this country by Dr. F. Crace Calvert, who exhibits (7433) a magnificent specimen prepared for medical purposes, and which fuses at 42.2° C. (108° F.). There is also a complete collection of the various forms of carbolic acid applied to curative and sanitary purposes. Messrs. Calvert state that the monthly sale by them of carbolic acid for medical purposes amounts to about seven thousand 8-oz. bottles, while there is a correspondingly large consumption of the preparations which contain from 10 to 20 per cent of the substance, especially the "carbolic acid soaps," and the convenient and efficient disinfectant known as "carbolic acid powder." A medal was awarded to this firm in 1867 for their monohydrate of phenol, the purity of which greatly enhanced the beauty of the colours obtained from carbolic acid, such as picric acid, rosolic acid, aurine, &c.

Actuated by a desire to see what such a destructive agent is really like, many of the visitors throng to the stand (7520) of specimens illustrating the manufacture and application of compressed gun-cotton exhibited by the Patent Safety Gun-Cotton Factory, formerly Messrs. Prentice and Co., of Stowmarket, Suffolk. This variety of gun-cotton is manufactured on Professor Abel's system; and as this eminent chemist is Official Reporter to the *Chemical Section*, it may not be uninteresting to quote the particulars of the system from the Report:—

"The starting point in the production of this gun-cotton is not cotton-wool, as was the case in Schönbein's original process, nor cotton of long staple spun into loose strands or threads, as employed in Von Lenk's system of manufacture. Any form of cotton refuse (*e.g.*, the so-called "machinery waste") may be employed, provided it be quite clean, and in a loose condition, so as to admit of its rapid impregnation by the acids with which it is treated. The process of converting the cotton into the most explosive form of gun-cotton or trinitro-cellulose, does not differ in any fundamental point from that first applied in 1846. The cotton, after being very carefully dried, is immersed, in small quantities at a time, in a perfectly cold mixture of one part of nitric (sp. gr. 1.15) and three parts of sulphuric acid (sp. gr. 1.85) and is afterwards allowed to remain for twenty-four hours in contact with about ten times its weight of the mixed acids, to ensure as complete a conversion as possible into gun-cotton. The vessels containing the cotton and acids are kept closed, and as cool as practicable; and, at the expiration of the proper period, their contents are transferred to a centrifugal extracting apparatus, by which the gun-cotton is separated to a very great extent from the excess of acid. It is then suddenly plunged, by means of simple mechanical arrangements, in very small quantities at a time, into a large volume of water. The object aimed at is to dilute the acid which remains in the gun-cotton with water so quickly as to avoid the development of heat, and the consequent establishment thereby of a second violently oxidising action of the nitric acid upon the gun-cotton—an action which, though only of the briefest

duration, would affect prejudicially the quality and perhaps also the stability of the product. The adoption of this precautionary measure, and the long-continued digestion of the gun-cotton with considerable excess of acids, constitute the prominent improvements which Baron Von Lenk effected in Schönbein's process for producing gun-cotton. After this preliminary washing, the gun-cotton is drained of water by means of the centrifugal extractor; it is then rinsed twice in a large volume of water, and passed through the centrifugal machine after each rinsing. It is now transferred to a rag engine of the kind ordinarily used in producing pulp for paper making. By this operation the gun-cotton is reduced to the state of fine division necessary for its subsequent conversion into homogeneous compressed masses; it is subjected, at the same time, to a most searching purification, which is continued in the next operation, the pulp being transferred to "poaching" engines, in which it is beaten about in a very large volume of slightly warm water, which is renewed from time to time. This final washing operation is carried on continuously until the gun-cotton has passed satisfactorily through a very searching test for purity, and generally lasts about 48 hours. This method of washing constitutes one of the great advantages of the present system of manufacture. The chief obstacle to the complete purification of the gun-cotton consisted formerly in the obstinate retention of impurities within the hollow fibres. With a view to their removal, Von Lenk prescribed continuous washing during many weeks in running water, and subsequent boiling with very dilute alkali. But by the application of the pulping and poaching processes, the capillary action of the fibre is greatly reduced, and the washing operation is rendered so searching that a decidedly more complete and uniform purification of the material is accomplished in three days, at the outside, than was previously attained by processes which extend over six or eight weeks. At the conclusion of the washing process, the gun-cotton pulp is converted, by a preliminary moulding process, and subsequently by hydraulic pressure, into compact masses of cylindrical and other forms of about the same density as water, and of dimensions suited to the particular applications required of them. During the whole of these manufacturing operations, the gun-cotton is wet, and therefore absolutely unflammable. After compression, the finished material is dried upon hot plates, which are freely open to the air at the sides, and is then packed in light wooden boxes for storage or transport. Compressed gun-cotton, prepared from the pulp as above described, possesses decided advantages over the forms of that explosive agent which have been previously manufactured, as regards compactness, uniformity, stability, and safety. It requires very strong confinement for the development of its explosive force by the ordinary modes of applying flame or heat; if inflamed in open air, or when confined in ordinary packing cases, it does not flash into a flame with explosive violence, like gun-cotton wool or yarn, but simply burns. It may, however, be made to explode with great violence in open air, and to exert a most powerfully destructive action, if fired through the agency of a detonation, such as is produced by the explosion of a small quantity of fulminate of mercury strongly confined. In this respect it resembles nitro-glycerine, and this property obviously renders it applicable, simple and expeditiously, to many important military, mining, and engineering operations. Unless gun-cotton be in the highly compressed form in which it is now produced, it is not susceptible of explosion *unless very strongly confined*. From the Patent Safety Co.'s works eight to ten tons of gun-cotton were sent out weekly. Government works are also in the course of completion for the extensive manufacture of compressed gun-cotton, which has been introduced into the Service for several military purposes, and as the explosive agent to be used in submarine mines.

Near at hand is an exhibit of Messrs. Rose and Gibson

(7522) of specimens of oil and paper prepared from cotton seed. The crop of American cotton gathered during the last season amounted to some 800,000 tons, and the weight of the seed to 1,958,620 tons, a quantity of cotton fibre, however, amounting to one-third the weight of the seed not being separated in the ginning. This has hitherto been waste, but is now utilised by Messrs. Rose and Gibson by passing the seed-husk with its fibrous coating between peculiarly constructed rollers to separate the kernel. A treatment with alkali is next effected, by which the fibre is loosened from the shell; it is afterwards washed and bleached. It is estimated that the seed of last year's cotton crop is capable of yielding 274,206 tons of fibre worth £30 per ton, besides 311,420 tons of crude oil worth £27 per ton, and 726,648 tons of oil-cake, worth £9 per ton as food for cattle. A case containing specimens of paper-pulp produced from wood (7551) is exhibited by Messrs. Smith and Granville; but no information is afforded as to the mode of treatment. The fibre is long and of fine colour.

Mr. Walter Weldon (7561) exhibits specimens illustrative of his process for the manufacture of chlorine. The *rationale* having been before the readers of this paper in previous numbers (see *CHEMICAL NEWS*, vol. xxii., No. 565, p. 145), it is unnecessary to enter upon details here. By the Weldon process of re-oxidising manganese, nearly 500 tons per week are being made. The cost of recovering the quantity of manganese required for the liberation of a given quantity of chlorine is less than one-fourth the average cost for the last five years of the native manganese required to do the same work. It will have been seen that the chemical exhibitors, although not numerous, present the result of much thought and labour; and all those in the least interested in technical production should at once visit the Exhibition who have not already done so. It closes with this month.

(To be continued.)

CORRESPONDENCE.

NEW FORMS OF GALVANIC BATTERIES.

To the Editor of the Chemical News.

SIR,—I send you a brief account of the results of my experiments on galvanic batteries. I tried some thousands of experiments, and kept batteries at work, watching them night and day for several months.

I soon found that the great point to secure constancy was a good negative. The positive is of minor importance, as the oxidation or other similar chemical change which takes place there produces a change of specific gravity in the liquid, securing a circulation and consequently a continuation of the action. This is much assisted by the action of heat, which itself, if applied at the bottom of the vessel, produces a circulation, and at the same time increases the conductivity of the fluid.

But the substances conveyed to the negative ordinarily cling there, and both by their chemical reaction and by forming a film on the surface soon immensely reduce the potential. This difficulty has been overcome in several ways, which I will proceed to discuss.

(1.) By a solution of copper, which absorbs hydrogen and produces metallic copper. Hitherto, this, on the whole, has been found the most convenient method for ordinary purposes, as in the Daniell battery. But to this there are many objections:—

1. Copper is not a very powerful negative, and to get a good potential requires an expensive positive, such as zinc, magnesium, &c., in order to secure much power. Copper and iron, for instance, are so near in their potential as not to give more than half the potential of copper and zinc, and consequently, when the expense of the negative is taken into consideration, the use of iron effects but little economy.

2. There is so much water of crystallisation in sulphate made to cling to it by dipping the cinders in a little of copper, that it requires very nearly four pounds to sulphoxidise one pound of zinc.

3. Sulphate of copper is not only rather insoluble, but is a nasty creeping salt, which is sure to find its way wherever you want to keep it out, and by getting to the zinc sets up a local action, wasteful and injurious. Every one who has used a Daniell battery for long knows how troublesome it is to keep in order.

The last difficulty may be obviated by using a neutral salt and silicate of soda with the zinc. The silicate precipitates the salts both of copper and zinc as silicates, and adds much to the steadiness and efficiency of the battery. With a mixture of nitrate and silicate of soda, magnesium may be used as a very powerful positive, and without any local action, which usually destroys it almost immediately. It is an expensive but most convenient and powerful positive.

(2.) By nitric acid with the negative to oxidise the hydrogen. This is very good for a short time, but the acid losing part of its oxygen soon becomes gaseous and fumes, both weakening the potential and proving very injurious to the health and comfort of any one subject to its influence.

(3.) Chromic acid. This, as chromic acid, though an excellent negative, is very expensive, being sold ordinarily at one shilling an ounce. Chromate of potassium, which is commonly used with sulphuric acid, is both expensive (being now I believe £90 per ton, wholesale) and very insoluble. Bichromate of soda is both much better and much cheaper (about £45 a ton now), but is difficult to procure, being sold only in lots of four tons. The potential of chromic acid is great—considerably greater than nitric acid—but soon becomes weaker, as it passes through the stages of chromoso-chromic, chromous oxide, &c.; mixed with nitric acid, it helps to stop the fumes, as chromous acid absorbs nitric oxide gas.

(4.) As far as I know, I have been the first to use the permanganates with acid; they are very powerful—more so than even chromic acid—but require adding gradually in order to supply oxygen, otherwise the oxygen flies off and the effect is lost. The action is so powerful that I have seen the wet coke electrode actually burst out into a flame on the first application of a permanganate with sulphuric acid. The permanganate of soda may be had at about £40 a ton, and therefore is not a very expensive source of oxygen.

(5.) As far as I know, too, I have been the first to use the chlorates, or chloride of lime (so called) with an acid; they are powerful negatives, but not so powerful as chromic or permanganic acid, and the evolution of chlorine in a gaseous form is objectionable.

(6.) Sulphate of mercury is expensive and very slowly soluble. Marie-Davy introduced it in France, but I hear it is now abandoned for sulphate of copper.

(7.) Peroxide of manganese. In some cases this is useful where a battery is very little used; but without acid it parts with its oxygen very slowly, and the Leclanché battery in which it is used very soon exhausts itself when put to do any hard work. At the Post Office after an hour's work, it has to be removed and a fresh one substituted till it has recovered itself.

(8.) My experiments at last led me to the conclusion that by far the best and cheapest negative is the air itself, which of course is practically used always in oxidising coal for producing power. For this purpose I pack the negative, carbon or platinum, in a high porous cell with cinders or similar material broken so as to be freely pervious to the atmosphere, and forming a damp porous bed, on the surface and pores and cavities of which the deoxidised materials may recover their oxygen. Thus the nitric oxide fumes are oxidised and flow back as nitroso-nitric acid; hydrogen is oxidised into water, especially if a little platinum black be sifted on the surface of the cinders and

becomes perfectly constant. If very hard work be required, the dimensions of the porous jar must be enlarged, and holes pierced above the level of the liquid to secure a good draught of air through the coke. The porous cell should of course only partially be filled with the liquid. I find the best plan is to put the zinc or iron in a neutral solution, which prevents the necessity of amalgamation, and to place in the porous cell with the carbon sulphuric and nitric acid in proportions proper for sulphoxidising the zinc. If sulphur be put in the cell with the zinc or iron, the oxidising of the sulphur will furnish the sulphuric acid, and save the necessity of sulphuric acid in the negative cell. With this negative iron may be advantageously used as a positive, as the potential of iron with a powerful negative is about $\frac{1}{3}$ of zinc, thus effecting a very considerable saving.

A very convenient battery is formed by using a solution of sulphate or muriate of ammonia for both parts of the cell. The acid unites with the zinc, and the ammonia and the hydrogen are oxidised on the coke, or partly oxidised, so as to form a solution of nitrate of ammonia, which itself acts over again.

Having obtained this excellent negative, I amused myself with trying almost every conceivable oxidisable substance as a positive. Of course a metal is quite unnecessary, any oxidisable liquid with carbon to collect the electricity being as effectual as a metal. Sulphur, a mixture of sulphur and carbonaceous matter (as in gunpowder), sugar, sawdust (especially with peroxide of manganese and sulphuric acid to decompose it), brandy and water, gruel, tea, broth, all gave good currents; the positive part of the cell acting the part of the stomach in the human body, and the porous cell with its cinders playing the part of the lungs. Again, all solutions of salts only partially oxidised, such as the hyposulphites, the cyanides, the sulphates, ferrous salts, gave exceedingly good currents, many of them fully as strong as a Daniell battery. The most powerful are of course the soluble sulphides, which in their first stages of oxidation are 60 or 70 per cent stronger than a Daniell, getting weaker as they go through the process of becoming sulphites and thionates. But as a hyposulphite is more valuable than a sulphide, the product after the first stage of oxidation is more valuable than the substance used, so that the electricity is got for less than nothing. Waste sulphide of calcium may thus become an important source of electrical and mechanical power. Heat, as it greatly increases the affinity of sulphur for oxygen, very much assists the action of these batteries. Again, ferrous sulphate gives an excellent current, and if we keep it in the condition of a ferrous salt by placing in it a sulphide of iron, forms a very cheap, indeed costless, source of electricity, because sulphate of iron is more valuable than a sulphide.

I will only add that I found that any common battery as the Wollaston, the Smee, and the Walker, if placed over a source of heat, so as to evolve steam from the negative, is made very powerful, and perfectly constant; the steam sweeping away the hydrogen from its surface. The common Walker battery is thus made equal to a Grove, and a Wollaston to a Daniell.

Now this production of cheap electricity opens a wide field for the substitution of magnetism for steam power. Even if Joule's theory were true, magnetic power could be produced as cheap as steam power. But I repeat, what I have written and explained privately to Dr. Joule, that his original experiments in 1843, when carefully and minutely examined, overthrow his own theory. Men like Sir W. Thomson and Tait doubtless do not like to be told that their elaborate science, built up mathematically with so much care and trouble, is based on a quicksand, and is inconsistent with facts. You know yourself how much odium and what violent attacks you have incurred by inserting my articles, which, though no doubt they contain mistakes, are in the main true. The British

Association absolutely refused to hear me, or even to admit a description of my batteries, lest, I presume, heresy should lurk even in them; but I noticed notwithstanding a considerable change in the tone in which both Sir W. Thomson and Tait spoke on the subject; though the latter took for granted the absurd supposition that -272° is the absolute zero of temperature, which idea I find good judges consider I conclusively disproved in an article some months since in the *CHEMICAL NEWS*; and where is the report of the committee appointed to determine the mechanical equivalent of heat? £50 was paid to them in 1870 for their expenses. What have they found to be the mechanical equivalent? They maintain a judicious silence themselves, though they are determined, as far as in them lies, to silence me too.

I urged a friend of mine, Mr. Slater, the optician, of 136, Euston Road, who has the apparatus required and well-constructed magnets, to try how much power he could get by electricity. He writes to me to say that, by accurate measurements and weighings, he has got 300 foot-pounds out of a grain of iron, and he is persuaded that by improved mechanism he could get at least six times as much. Now, even 300 foot-pounds to a grain of iron is only nine pounds of iron per day of ten hours for a horse-power, a cost which may vie with steam in economy. And taking sulphide of calcium or of iron instead of iron, we can reduce the cost per horse-power to a mere trifle. The only question is the cost and convenience of the machinery. Even if the American statements are an exaggeration, this question must soon be the question of the day for all mechanists and engineers.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney,
Sept. 18, 1871.

PS.—Since writing my letter, my ingenious friend Mr. Slater, by a larger battery, has obtained 1,371,088 foot-pounds of work from 7 ounces of iron, or 388 per grain; this with two electro-magnets rotating before a fixed electro-magnet.—H. H.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 14, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

New Volatile and Sweet Principle found in the Caoutchouc of Bornéo.—A. Girard.—After briefly referring to his researches (in 1862) on dambonite, $C_8H_8O_6$, a sweet saccharine substance found in the caoutchouc of Gabon, and on dambose, $C_8H_8O_6$, a derivative from dambonite by the action thereupon of hydriodic acid, the author communicates the results of his researches on the caoutchoucs obtained from climbing plants belonging to the genus *Urceola*, and grown in Madagascar as well as in Bornéo. These kinds of caoutchouc contain, enclosed among the real caoutchouc substance, a body, very soluble in water, which the author has named *Bornesite*, which in pure state is a crystalline solid body difficultly soluble in strong alcohol, which fuses at 175° without decomposition, and sublimes at 205° with but partial decomposition. Bornesite is not capable of undergoing fermentation, and does not reduce the cupro-potassic tartrate solution unless it has been first acted upon by very dilute sulphuric acid. Treated with nitro-sulphuric acid, bornesite is converted into a nitrated crystalline body, insoluble in water, soluble in alcohol, fusing at about 35° , and detonating by a blow. The formula of bornesite is $C_{12}H_{12}O_{12}$; treated with an excess of hydriodic acid, at 120° in a

sealed tube, it yields, as does dambonite, ether methyl-iodhydric and dambose. While neither dambonite nor dambose act at all upon polarised light, bornesite was found to be dextrogyrate.

Influence Exercised by the Difference of Size of the Polar Electrodes of a Galvanic Battery.—T. Du Moncel.—The contents of this paper and of the following are not suited for useful abstraction.

Molecular Properties of Saline Solutions considered according to the Densities thereof.—C. A. Valsen.

Apparent Volatilisation of Silicon and Boron.—L. Troost and P. Hautefeuille.—The authors describe in this lengthy memoir a series of experiments made with pure silicon and boron, each by itself, placed in porcelain tubes, kept at a very high temperature (in a slow current of dry and pure hydrogen gas), and the reaction which ensues by the admission, into the tube, of fluoride of silicon, chloride of silicon, and fluoride of boron. Silicon is under these conditions apparently volatilised, forming a brown-coloured smoke, which, in a cooler part of the tube, is condensed sometimes as amorphous silicon, sometimes deposited in crystalline state. The same obtains with boron, but this apparent volatilisation is due to a simple mechanical effect, conjointly with the existence of compounds of silicon with chlorine and fluorine which are only formed at a very high temperature and dissociated at red heat.

Thermo-Chemical Researches on the Cyanogen Series.—Dr. Berthelot.—This essay contains the following sections:—Cyanhydric acid; potassium cyanide; cyanhydrate of ammonia; cyanide of mercury; cyanate of potassa; chloride of cyanogen; iodide of cyanogen; bromide of cyanogen.

Production of Ammonia by the Alcoholic Fermentation.—M. Dubrunfaut.

Presence of Milk Sugar in a Juice of Vegetable Origin.—Dr. G. Bouchardat.—The author relates at length a series of experiments made with a specimen of sugar obtained (1837) from the juice of the *Achras sapota*, at Martinique, the specimen being preserved among the objects known as belonging to the *Matière Médicale de Morat*. By treating a portion of the sample of the sugar alluded to with boiling alcohol at 90 per cent, there was left undissolved a substance which, on further investigation, was found to possess all the physical and chemical properties of milk sugar. A careful quantitative analysis of the sample established the fact that it contains 55 per cent of cane sugar and 45 per cent of milk sugar, which latter was also found to exist in the ripe fruit of the same tree recently brought from Egypt and analysed by the author.

This number also contains several important papers relating to meteorology.

August 21, 1871.

This number contains the following papers and memoirs relating to chemistry and collateral sciences:—

Quantitative Estimation of Nitrous and Nitric Acids in Rain-water.—M. Chabrier.—This essay contains, in tabulated form, the results of a series of experiments made chiefly at Saint-Chamais (Bouches du Rhône). It appears that, contrary to what is generally supposed to be the case, nitrous acid is far more generally present in rain-water than nitric acid, while nitrite of ammonia has also been found by the author; the quantity of nitrous acid in the litre of rain-water amounts to from 0.7 to 0.8 milligramme, the quantity of ammonia to from 0.30 to 0.35 milligramme, while of nitric acid only traces are found. Curiously, the quantity of rain which falls in the part of France above alluded to is the same as the quantity which falls in Paris, but in the former instance there are only fifty rainy days, to at least three times as many in the latter.

Petroleum and Paraffin Oils.—M. d'Abbadie de Barrau.—A letter addressed by the gentleman just named to the Academy, with the view of receiving the opinion of that scientific body on a process of fractional distillation executable on the large scale, and so contrived as to render the oils used for burning in lamps unflammable without wicks at a temperature above 65° (156° to 158° F.), while the heavy oils are rendered suitable to be burnt in *modérateur* lamps without producing smoke and emitting an unpleasant smell.

Experiments on the Conversion of Mechanical Force into Heat.—P. Volpicelli.

New Contribution to the History of Carbon.—Dr. Berthelot.—In the first part of this very lengthy essay the author treats on the properties of the carbon met with in the Cranbourne (near Melbourne, Australia) meteorite; this carbon must be considered as having been first in state of solution in molten iron, and to have separated therefrom on cooling. Next, the carbon obtained from oxide of carbon, by the decomposition of that gas by iron at a relatively low temperature, is considered. From the reactions of these substances, the author comes to the conclusion that native graphite, about the origin of which very little is known, is certainly not, at least as far as experiments can throw light on this point, derived from either anthracite or from decomposed masses of meteoric iron which contained carbon.

Reagent for Alcohol.—Dr. Berthelot.—When benzoic chloride, C_6H_5COCl , is put into contact with water it is only very slowly decomposed, but if the water contains any alcohol (even as little as 1 in 1000 parts of water) benzoic ether is at once formed; this ether is set free by a single drop of aqueous solution of caustic potassa, the odour of the ether being very peculiar and prominent.

Note on a Subchloride of Silicon.—C. Friedel.—After referring to formed researches on the silicon compounds, and to the researches of Troost and Hautefeuille, the author states that when hexiodide of silicon, Si_2I_6 , is heated along with bichloride of mercury, there is formed, along with tetrachloride of silicon, another less volatile silicon chloride, Si_2Cl_6 , and an oxychloride of silicon, Si_2OCl_4 . By

passing chloride of silicon vapours over solid silicon, placed in a porcelain tube, heated to a very high temperature, beside acicular silicon crystals, very hard solid agglomerated silicon was obtained in sufficient quantity to serve instead of carbon (graphite) as conductors for electricity and the production of electric light.

Petroleum Oils of the Bas Rhin.—M. Le Bel.—The contents of this paper contain an account of the various hydrocarbons obtainable from bituminous shale, which is submitted to dry distillation for the purpose of manufacturing what is, in this country, generally termed paraffin oil. The author has obtained hydride of amyl, hydride of hexyl, and compounds of these bodies from the oil alluded to after having been treated with sulphuric acid.

Some Metallic Trichloracetates.—A. Clermont.—This paper treats on:—Trichloracetate of baryta, $C_2Cl_3O_2, BaO + 6HO$, a crystalline, but very deliquescent, salt; trichloracetate of strontia— $C_2Cl_3O_2, SrO + 6HO$,

also a crystalline salt, less deliquescent than the preceding, but readily soluble in water; trichloracetate of lime; and trichloracetate of soda.

This number also contains several papers on astronomy, meteorology, and geology.

Polytechnisches Journal von Dingler, first number for August, 1871.

The following papers and essays relating to chemistry and collateral sciences are contained in this number:—

Studies on Blast-Furnaces for Iron-Works.—C. Schinz.—The first portion of a lengthy monograph on this subject containing the following sections:—Introduction; statics of temperature in blast-furnaces; utility and purpose of the statics of temperature.

Method of Removing and Utilising Phosphoric Acid from Iron Ores.—J. Jacobi.—The author proposes to convert the phosphoric acid present in many ores into a soluble state, by treating the same with sulphurous acid and water, to be forced into the previously ground up ores by means of properly constructed machinery. The ore is next washed with water, and the phosphoric acid solution applied for agricultural manure.

Description of an Apparatus for Determining the Melting-Point of Organic Substances.—J. Löwe.—Illustrated with engravings. It appears that, for accuracy of results and nicety of means of observation, this contrivance deserves special notice. The description requires the aid of engravings.

Extraction of Animal Fats to be used either as Food or for Cosmetic Purposes.—Dr. H. Vohl.—The fresh fat is first as much as possible freed from membranes and flesh, next cut up either into small discs or cubes, and then thoroughly washed with cold water (which should contain the least possible quantity of lime, therefore fresh river-, or, better, good rain-water, should be used) until all blood is entirely removed. The fat is next put into a cylindrical stoneware vessel, 125 metres high and 0.5 metre inside diameter, this vessel being placed in a water-bath and provided with a tap at the bottom, so placed that the vessel may be emptied without removing it from the water-bath. The vessel having been filled for three-fourths of its capacity with fat, there is placed on the top of it a stoneware perforated disc, and next poured over it (the fat) very dilute pure hydrochloric acid—10 per cent of the weight of the fat of an acid made up of 3 lbs. of chemically pure HCl at 1.12 sp. gr. to 100 lbs. of water (sulphuric acid is not to be substituted, because its solvent power for membranes is very slight). This having been done, the stoneware vessel is closed with a well-fitting cover, and the water-bath heated. From the fat, while melting, the perforated cover carries, by slowly sinking downwards, all the impurities, as far as they are not dissolved by the acid, which at the end of the operation is run off by aid of the tap. The fat is then, while yet molten, washed several times with warm water, to which, for the last washing, some carbonate of magnesia is added. The acid liquid yields, along with phosphate or other native phosphate of lime, an excellent manure. The fat is next treated with Canada oil (a refined petroleum spirit), and the solution separated by decantation from any yet present nitrogenous organic matter (membranes, &c.). The solution of the fat is freed by distillation (in a water-bath) from the Canada oil, and the result is the production of a very superior fat, which, being absolutely free from water and other organic, especially nitrogenous, matter, is not liable to become rancid, and may be preserved for many years. Although the process here briefly described may appear complicated, it yields not only a better, but also far larger quantity of product.

Description of a Diffusion Apparatus for the Purpose of Exhausting the Active Principles from Vegetable Matter, and especially for Extracting, by means of Cold Water, Sugar from Beet-Root Pulp.—J. Robert.—With engravings.

Preparation of Fruit Juices.—U. Gröger.—A lengthy paper treating on the preparation of syrups from various kinds of fruit.

Prize Essay for the Estimation of the Value of Raw Beet-Root Sugar.—The directors of the Association for the beet-root sugar industry in the German Customs Union (*Zollverein*) considering that the coefficient γ , adopted by the French trade as measure for the melassimetric value of the salts contained in raw beet-root sugar, is not founded on scientific basis, have resolved to grant a sum of £150 for the best essay to the following query:—Since the quantity of crystallised white sugar contained in various samples of raw beet-root sugar does not stand in direct relation to the polarisation, what research (analysis) and calculations are to be made to estimate theoretically beforehand the yield (*rendement*) of white crystalline sugar contained in a sample of a raw beet-root sugar? If it happen that a complete and, in all respects, satisfactory answer to this ques-

tion be not sent in, the nearest approaching solution of the problem will be paid for in a proportionate manner. The essays, to be written in German, to be sent, postage or carriage paid, on or before the 31st of January next, to Dr. Riedel, Privy Councillor, &c., 76, Klosterstrasse, Berlin. The decision and award of the directors will be made at their general meeting, May, 1872.

Annalen der Chemie und Pharmacie, August, 1871.

This number contains the following original papers and essays:—

Researches on the Constitution of Piperine and of the Products of its Dissociation—viz., Piperinic Acid and Piperidine. —R. Fittig and T. Remsen.—The second instalment of the lengthy monograph on this subject, containing the following sections:—Action of nascent hydrogen upon piperonal; hydro-piperone, $C_{15}H_{11}O_6$; action of chloracetyl and of nitric acid upon hydro-piperone; isohydro-piperone; piperonyl-alcohol, $C_{15}H_{13}O_4$; action of nascent hydrogen upon piperonylic acid; action of hydrate of baryta, dilute hydrochloric acid, and water upon piperonylic acid; action of chloride of phosphorus upon piperonal; action of hot water upon dichlor-piperonal; action of chloride of phosphorus upon piperonylic acid; constitutional formulæ of the bodies treated of.

Volumetrical Estimation of the Typical Hydrogen in the Ammonia Bases, and on the Reactions Exhibited by Free Phenol-Hydroxyloxy.—H. Schiff.—The first portion of this paper is not suited for abstraction. From the second portion we quote the following:—The non-nitrogenous aromatic substances which are coloured by chloride of iron contain free phenyl-hydroxyloxy; this reaction ceases when, for the hydrogen of the hydroxyloxy, are substituted other groups. Nitro-derivatives either do not exhibit this reaction at all, or only in a very limited manner; the intensity of this coloured reaction appears to depend upon the number of the free hydroxyloxy present in the substances.

Researches on Glycerine and Allyl Compounds and their Behaviour towards each other.—H. Hübner and K. Müller.—This memoir, treating on the position of the constituent atoms of allyl-alcohol and derivatives obtained therefrom, contains the following sections:—Dichlorhydrine; decomposition of dichlorhydrine by sodium; conversion of dichlorhydrine into an isomeric dichlorhydrine; decomposition of epichlorhydrine by sodium.

Potassium Amalgam—Sodium Amalgam.—K. Kraut and O. Popp.—The authors describe a series of experiments made with solutions of carbonate of potassa of different strength, into which sodium amalgam was placed and left for longer or shorter time, the result being the formation of a crystalline potassium amalgam, mixed, however, with a very small quantity of sodium, which the authors consider to have been left in combination with the mercury. The percentage composition of several of the amalgams thus obtained is quoted; as instances, we mention the following:—Hg, 98.370; K, 1.560; Na, 0.036. Hg, 98.420; K, 1.31; Na, 0.119. Hg, 98.044; K, 0.934; Na, 0.641. Potassium amalgam—formula, K_2Hg_{24} ; in percentages—Hg, 98.41; K, 1.59. Sodium amalgam, Na_2Hg_{12} , with 1.88 per cent sodium.

Phenyl Ether and Diphenyl-Oxide.—W. Hoffmeister.—This lengthy and very exhaustive monograph contains the following chapters:—Preparation of phenyl-ether by means of sulphate of diazobenzene and phenol; preparation of phenyl-ether from benzoate of copper; properties of phenyl-ether, and its behaviour with pentachloride of phosphorus, zinc-dust, chromic, sulphuric, and hydriodic acids; phenyl-oxide-bisulpho acid; binitro-phenyl-ether; biamidophenyl-ether; bibrom-phenyl-ether; diphenyl-oxide; diphenyl-oxide-bisulpho acid; binitro-diphenyl-oxide; bibrom-diphenyl-oxide.

Disulphobenzoic and a New Dioxybenzoic Acid.—L. Barth and K. Senhofer.—This essay contains a complete description of the mode of preparation and the salts of the two acids alluded to. The disulphobenzoic barium compound has the formula—

The formula of the new dioxybenzoic acid is $C_7H_6O_4 + 1\frac{1}{2}H_2O$.

Conversion of Oxymethylene into Protocatechetic Acid, and on the Constitution of the latter.—L. Barth.

Bimethyl- and Biethyl-Protocatechetic Acid.—R. Koelle.—Bimethyl-protocatechetic acid is a solid crystalline substance, not yielding with chloride of iron the reaction protocatechetic acid yields with that compound. It is a strong acid; formula—

Some of the salts of this acid are described. The biethyl-protocatechetic acid—

is also a solid body, crystalline, and fusing at 149°.

Conversion of Dichloracetone into Lactic Acid.—E. Linneman and V. von Zotta.—When dichloracetone is submitted in sealed tubes to a temperature of 200° along with water (20 volumes), it is converted into lactic acid. 24 grms. of dichloracetone yielded 5 grms. of pure lactate of zinc.

Stannum Triethyl-Phenyl.—A. Ladenburg.—This substance is a colourless liquid, which is readily oxidised by exposure to air, insoluble in water, readily soluble in ether and absolute alcohol, and boils at 254°; sp. gr. at 0°, 1.2639. Formula, $Sn(C_2H_5)_3C_6H_5$.

Silico-Propionic Acid and its Ether.—C. Friedel and A. Ladenburg.—Notwithstanding the high scientific merits of this paper, its contents are not suited for any useful abstraction.

Preparation of Hydrochlorate of Creatinin from Urine.—R. Maly.—Several litres of urine are first concentrated to one-fourth of its bulk by evaporation, decanted from the sediment of salts, the fluid treated with acetate of lead, filtered, and the excess of lead contained in the filtrate removed by sulphuretted hydrogen, and the filtered liquid nearly neutralised with soda. After this, a concentrated solution of corrosive sublimate is added, whereby a compound of creatinin and mercury is thrown down, which, having been decomposed by sulphuretted hydrogen, is next treated with animal charcoal, and after that evaporated to dryness. The resulting crystalline mass is treated with alcohol, and leaves, on evaporation, creatinin in pure crystalline state.

The American Journal of Science and Arts, August, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Historical Notes on the Systems of Weather Telegraphy and Especially their Development in the United States.—Dr. C. Abbe.—A very excellent account of what has been done in this respect by Americans, to whom, jointly with Europeans, the honour is due of having initiated weather telegraphy, and brought it into practice.

Tornadoes in the Southern States.—H. S. Whitfield.—This essay contains an excellent and clearly-written account of this phenomenon and the causes which produce it.

New Difference Engine.—G. B. Grant.—Illustrated by woodcuts. It treats on the subject of calculating machines.

New Form of Galvanometer.—J. Trowbridge.—Illustrated by an engraving required for the proper understanding of this subject.

Notice of the Meteoric Stone of Searsmont, Maine.—C. U. Shepard.—Account of the phenomena which were observed at the fall, accompanied by a loud report, as of the firing of heavy ordnance, on May 21 last at the locality above named, and exhaustive description of the external physical appearance of a small fragment of the meteorite, the fragments of which, scattered far and wide, are now difficult to find.

This number also contains a number of papers bearing upon natural history.

NOTES AND QUERIES.

Palm Oil.—(Reply to "Chemicus")—As regards the bleaching and decolorising of palm oil, bichromate of potassa and dilute sulphuric acid are used. A work now in the press, viz., Wagner's "Technology" (Churchill), will give you full details on this subject.

Lute for Nitric Acid.—(Reply to "Chemicus.")—Use fire-clay, or better still, kaoline as lute after having thoroughly mixed it with a tolerably strong solution of silicate of soda. Consult the former volumes of the *CHEMICAL NEWS*, since many lutes and cements are mentioned therein.

Soda from Cryolite.—There appeared in the *CHEMICAL NEWS*, vol. xxiii., p. 270, an account of the "Manufacture of Soda and Carbonate of Soda from Cryolite," by Mr. J. L. Smith. I have conducted some experiments with a view to making caustic soda liquor from cryolite, observing the directions given in the above process, as described by Mr. Smith. I treated the crushed cryolite with 15 parts of lime, and after boiling for three hours, I found that decomposition had been effected, although I failed to obtain certain results that ought to remain, according to Mr. Smith's calculations. I obtained caustic soda liquor at 22° T., but it was contaminated with alumina in some form. I estimated the alumina, and I found in the gallon of liquor, which consisted of strong caustic soda washings, 585 grs. of alumina. I would feel much obliged if either Mr. J. L. Smith or any other chemist would inform me how to separate the alumina without destroying the causticity of the soda solution. I would like to be informed, also, of the price per ton of cryolite, delivered, say, in London. I have written to Copenhagen for this last particular, but have not had any reply.—W. F. CATCHESINE, F.C.S.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, applied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871–1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c. All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HICKIN'S HIEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under 4 per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under 4 per cent.

GASKELL, DEACON, & CO.,
ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

THE CHEMICAL NEWS.

VOL. XXIV. No. 618.

ON THE OXIDATION PRODUCTS OF ESSENTIAL OIL OF ORANGE-PEEL (EAU DE PORTUGAL).*

By C. R. A. WRIGHT, D.Sc., and CHARLES H. PIESSE.

Preliminary Notice.

THE researches of Soubeiran and Capitaine, and those of Dr. Gladstone, have shown that there is contained in oil of orange-peel a hydrocarbon, hesperidene, boiling at 174° , and of formula $C_{10}H_{16}$; the oil employed in these experiments (which was kindly furnished for this purpose by Messrs. Piesse and Lubin, and was believed to be a perfectly pure and genuine article) began to boil at 175° , and almost entirely distilled below 180° ; a small amount of non-volatile resinous yellow substance was left in the retort; this was almost insoluble in alcohol when cold, and but slightly so when boiling. After complete expulsion of hesperidene it furnished a soft resin not hardening on standing, perfectly inodorous, of a bitter aromatic taste, and yielding the following numbers on combustion:—

0.3595 grm. gave 0.997 CO_2 , and 0.314 H_2O .

	Calculated.	Found.
C_{20}	240	75.47
H_{30}	30	9.43
O_3	48	15.10

$C_{20}H_{30}O_3$ 318 100.00

No nitrogen was contained in this body, which appears to be related in composition to the hydrocarbon hesperidene; the amount of this resin in the specimen of oil examined was 2.8 per cent.

On re-distilling the hydrocarbon over sodium, scarcely any action ensued; the whole came over between 175° and 177° (uncorrected). Treated with nitric acid and warmed, a powerful action ensues. By employing acid diluted with its own bulk of water, this action is moderated, and may be safely performed in a capacious flask furnished with an inverted condenser, red fumes and CO_2 being copiously evolved. By employing about 1 volume of hydrocarbon, 3 of nitric acid, and 3 of water, and boiling for $1\frac{1}{2}$ hours, a brown resinous non-volatile substance is obtained, which may be obtained pure by boiling several times with water, and drying at 100° , at which temperature it becomes soft; this resin contains nitrogen, and on combustion gave—

Carbon	57.0 per cent
Hydrogen	5.9 "

By the further action of diluted nitric acid on this resin, a yellow resin is produced which does not soften at 100° . A specimen obtained by the action of 1 volume of hydrocarbon, 3 of nitric acid, and 3 of water, for $1\frac{1}{2}$ hours, another volume of nitric acid being then added (red fumes having almost ceased to come off), and the whole boiled 1 hour longer, gave these numbers—

Carbon	47.4 per cent
Hydrogen	5.1 "

Both this resin and the former brown one appear to contain less hydrogen in proportion to the carbon than the original hydrocarbon, the ratios being—

	Carbon.	Hydrogen.
Hesperidene	100	13.3
Brown resin	100	10.3
Yellow resin	100	10.9

As both contain nitrogen it is possible that they may be derived from $C_{10}H_{16}$ by addition of oxygen and replacement of H by NO_2 .

The aqueous acid from which these resins have separated contains much oxalic acid (recognised by combustion, and the behaviour of its calcium and manganese salts, and the explosibility of its silver salt), and apparently also another acid containing nitrogen; for the snow-white oxalic acid prepared by precipitation as lead salt, treatment with H_2S , and several recrystallisations from water, did not give perfectly sharp numbers on analysis, and was found to contain nitrogen by the sodium test.

When hesperidene is boiled *per ascensum* for several hours with dilute potassium dichromate solution, and about as much SO_4H_2 as will saturate the metals of that salt, CO_2 is slowly given off and the chromate is reduced. On distilling the product of five hours' action of 1 part hydrocarbon, 3 of chromate, 1 of SO_4H_2 , and 30 of water, an acid distillate was obtained, as well as an oily substance, consisting for the most part of unaltered hesperidene; this oily body, however, although volatile with steam of water, does not wholly volatilise at the temperature at which the original hydrocarbon distils (175° to 177°), a portion being found to boil at a temperature higher than 200° .

The acid distillate, converted into barium salt, gave a product that reduced silver nitrate on boiling, gave a red colouration with ferric chloride, a strong smell of acetic acid on warming with SO_4H_2 , and of acetic ether with alcohol and SO_4H_2 ; the barium salt gave these numbers—

0.2765 gave 0.245 $BaSO_4$ Ba = 52.1 per cent.
Barium acetate requires .. 53.7 "

From these numbers it appears as though a trace of some acid of higher molecular weight than acetic were produced, especially as probably a little formic acid is also present (from the reduction of the silver nitrate); still the main portion of the product is acetic acid, as is shown by the following analysis of the silver salt obtained by double decomposition of the barium salt by $AgNO_3$, and three re-crystallisations from boiling water.

0.309 gave 0.200 Ag Ag = 64.7 per cent
Silver acetate requires 64.7 "

This production of acetic acid does not arise from admixtures of any other body with the hydrocarbons, as might possibly be imagined; in the first place, the high commencing boiling-point of the oil, and its constancy indicates that, at any rate, only traces of any other substance could be present; and, again, the hydrocarbon regained from the oily substance arising from the reaction of the chromate, &c., on hesperidene, furnished more acetic acid on again subjecting it to this treatment.

From the production of acetic acid it appears that the group CH_3 must be present in hesperidene; the following formula—

possibly may express its composition. It is proposed to follow up these experiments so as to gain some clue to the functions of the other eight carbon atoms, and also to submit other similar substances to examination in the hope of throwing some light on the question of "physical isomerism" in the turpentine group of hydrocarbons.

Manganese dioxide and sulphuric acid do not seem to produce any promising results with hesperidene. The action of potassium chlorate and SO_4H_2 is very marked, a thick resinous substance being formed.

* Read before the British Association, Edinburgh Meeting, Section B.

ON A NEW METHOD OF ESTIMATING ZINC.

By HUGO TAMM.

Of all the metallic precipitates which abound in chemistry there is none which can be compared to hydrated sulphide of zinc. In forming it nature seems to have made a gross mistake which she carefully avoided in the creation of the congener metal *magnesium*, for this abominable compound possesses all the bad or negative properties of all the others, without almost a single good one as a compensation. It settles too slowly in liquors, and when once settled, rises up too quickly if an attempt is made to decant the liquid. It clogs the filters; it passes through the filters; it washes only when it chooses; it oxidises at pleasure, but invariably at the wrong moment; it refuses to oxidise when required to do so; or, when it oxidises, it retains both sulphur and oxygen, seemingly, for the very purpose of leading to wrong results. And yet chemists have, for ages past, submitted to this intractable substance, and all the modes of estimating zinc are founded on the use of sulphide of zinc.

After some efforts, I have succeeded in shaking off the yoke of this capricious mineral tyrant. I am far from saying that this new method is perfect. I shall carefully point out its defects; but, in most cases, where zinc is specially looked for, it is by far the easiest and safest method, and its general convenience is an ample compensation for its defects, which, on the whole, are but slight. After endeavouring, but in vain, to discover some volatile substance which would precipitate zinc completely in acid solutions, or some substance not difficult of separation from any of the elements likely to co-exist with zinc, and precipitating zinc in acid or neutral liquors, according to the rules which I have laid down elsewhere, I was led by analogy to apply the method which answers so well—in default of a better one—for the estimation of magnesia, and I studied the action of phosphates and ammoniacal salts on zinc solutions, and I found that phosphate of soda, for instance, precipitates completely a neutral or slightly acid solution of chloride of zinc, mixed with an excess of chloride of ammonium, in the state of phosphate of zinc and ammonia.

It is this reaction which I have applied with the greatest success to the estimation and separation of zinc in most cases where the estimation of this metal is of any importance.

Preparation of Ammonio-zincic Phosphate—Behaviour and Composition of this Salt—Value of this Mode of Estimating Zinc.

When a solution of zinc in any mineral or volatile organic acid is supersaturated by ammonia, until all the oxide of zinc is dissolved, and when this solution is re-saturated by hydrochloric acid until litmus paper indicates a feeble acid reaction, a double chloride of zinc and ammonium exists in the liquor. If a solution of ordinary crystallised phosphate of soda is added, a voluminous white precipitate of phosphate of zinc is formed, which, if left for a few minutes at a temperature near that of boiling-point of the liquor, soon combines with phosphate of ammonia, and suddenly comes down, in the shape of a dense white precipitate, which settles very rapidly.

This precipitate of ammonio-zincic phosphate, collected on a filter, can be washed with the utmost facility, in fact, as fast as water can be poured upon it, and it never passes through filters, a most important property. It retains the phosphate of soda and chloride of ammonium in the midst of which it has been precipitated with some strength, and several successive washings are absolutely required to free it from these salts, but eventually the washing is complete. To ascertain this, nitrate of silver acidulated with nitric acid must be used, because the double phosphate retains chlorides with more strength than phosphates.

After drying at 100° C., the ammonio-zincic phosphate has the constant formula—

and it contains exactly 36.49 per cent of metallic zinc.

From a careful examination of this salt, I arrived at the conclusion that the equivalent of zinc is 32.75. On this point I agree with some analysts, and differ from others. I will not, however, discuss this question, suffice it to say that in complete analyses I have arrived at more exact results in taking the equivalent of zinc at 32.75 than in taking it at 32.

Calcined over a gas-lamp, the double phosphate leaves a residue of pyrophosphate of zinc, $(\text{ZnO})_2\text{PhO}_5$.

It might be supposed that zinc could be estimated with accuracy in this salt; but this is not the case, as a loss of zinc is always incurred during the calcination of the ammonio-zincic phosphate. On the contrary, the composition of the phosphate of zinc and ammonia, well washed and dried at 100° C., can always be relied upon, and it is from the weight of this salt that the amount of zinc must be calculated.

The precipitation of zinc is complete when the supernatant liquid, mixed with a little excess of phosphate of soda, does not show any bulky precipitate of zinc phosphate; but it is advisable to add at once to the zinc solution a quantity of phosphate of soda, sufficient to turn red litmus paper blue. The liquor is only momentarily alkaline, and it re-assumes its slightly acid or neutral reaction as soon as the double phosphate has come down, so that the precipitation actually takes place in a slightly acid or neutral liquor, a gratifying result.

Should a very accurate estimation of zinc be required, the liquor should be left in a warm place for some ten or twelve hours, when the precipitation of the zinc will be very complete, as might be proved by adding sulphide of ammonium to the filtrated liquor, or sulphuretted hydrogen to the filtrate previously saturated by ammonia, and re-acidulated by acetic acid. In general a trace of zinc is precipitated, for the double phosphate is not absolutely insoluble. For most practical purposes, it is quite sufficient to allow the precipitated double phosphate to rest for about an hour; a very small quantity of zinc will remain in the liquor, from which it can be separated by sulphide of ammonium, but this quantity of zinc never amounts to more than 1-300th of the quantity of zinc precipitated by phosphate of soda, so that it can be neglected, especially if a simple assay of zinc is all that is required.

One of the chief defects of the double phosphate is its propensity to adhering firmly to the side of the flask in which the precipitation takes place. A thin film of this salt coats the glass, and it can be removed only with some difficulty. A glass stirrer, covered at one end with 1 inch or 1½ inches of india-rubber tubing, can be advantageously employed for this purpose. But it is best, after the bulk of the precipitate has been removed on the filter, to dissolve the adhering film in dilute hydrochloric acid, to neutralise by ammonia, to add a few drops of phosphate of soda, to boil, and to add the slight precipitate thus obtained to the main portion already placed on the double filter.

It is sometimes possible to avoid the coating of the glass with ammonio-zincic phosphate, by heating the solution almost to boiling-point before adding phosphate of soda; the precipitation in this case is very rapid, and, by taking this precaution, further trouble is avoided. But the chief defect of this mode of estimating zinc is undoubtedly the use of phosphate of soda, a fixed salt, difficult of separation from most substances. Unfortunately, with zinc, there is no choice of precipitating reagents, and phosphate of soda, which must be considered as a very perfect assay reagent, is, from its very nature, a defective one in analytical researches.

If, in similar conditions, carbonate of ammonia is substituted for phosphate of soda, most of the zinc is precipitated as ammonio-zincic carbonate, but, even when the operation is conducted with the utmost care, too large a proportion of zinc remains in the liquor. On the other

hand, if carbonate of soda is used, no precipitation of zinc takes place. However, in such cases as this one, the only remedy is a complete knowledge of the behaviour of the reagent employed in given instances, and I shall, accordingly, expose the result of my observations.

Estimation of Zinc in Spelter, and in Salts and Compounds chiefly formed of Zinc and of Oxide of Zinc.

Fifty grains of spelter, and from 50 to 100 grains of the zinc salts or compounds, are dissolved in dilute hydrochloric acid. The solution is supersaturated by ammonia, and a little carbonate of ammonia is added to precipitate any lead which might be present. The addition of carbonate of ammonia, which is essential in the case of spelter, may be useless with other zinc solutions, and, as its effervescence with acids is a source of trouble, it ought to be used only for a purpose. If lime exists in the solution, it is, of course, just as well to get rid of it at once by using a little carbonate of ammonia.

The liquor, separated from any precipitate produced by ammonia or carbonate of ammonia, is re-saturated by hydrochloric acid, until blue litmus paper indicates a feeble acid reaction. The liquor is brought to almost boiling point, phosphate of soda is added until red litmus paper turns blue; the liquor is kept at about the same temperature until the double phosphate has come down; it is then tested for zinc with phosphate of soda, and when the precipitation is complete, the whole is left for some time in a warm place. After filtering, washing, and drying the precipitate, with the precautions already indicated, the amount of zinc is calculated from its weight.

Estimation of Zinc in Blendes.

There are two classes of blendes: those which contain large proportions of iron and small proportions of lead, and those which contain large proportions of lead and small proportions of iron.

Blendes of the first description are attacked by strong nitric acid, and, when the action is over, a large excess of hydrochloric acid is added, then hot water in sufficient quantity to give a clear liquor.

After cooling, the mixture is supersaturated by ammonia. The whole is then boiled and filtered, the precipitated oxide of iron is well washed with dilute ammonia, then re-dissolved on the filter in hydrochloric acid in excess, re-precipitated by ammonia, re-filtered, and well washed.

This second treatment of the oxide of iron is absolutely necessary, but it is most efficient. I have assured myself, by the most careful investigation, that, after this double treatment, the oxide of iron *does not contain a trace of zinc*. This result must be attributed to the large excess of chloride of ammonium formed during both operations.

In this result, I differ from that admirable chemist, H. Rose, who condemns this method of separating zinc from iron. But I suspect that he had not observed the excellent influence of an excess of chloride of ammonium, for if this salt does not exist in the liquor, or if it exists only in small proportion, it is quite true that the separation of zinc from iron by ammonia is impossible.

With the second class of blendes, addition of a large excess of hydrochloric acid is not required. The blende is attacked by strong nitric acid, a little hydrochloric acid is added, then water, then an excess of ammonia, and, lastly, a quantity of carbonate of ammonia sufficient to precipitate thoroughly all the lead. The whole is boiled and filtered, and the precipitate is well washed with water containing a little ammonia and carbonate of ammonia. The precipitate is re-dissolved on the filter in nitric acid, and submitted once more to a treatment similar to the first.

In analyses, the more complicated modes of separation of zinc from iron and lead would have to be resorted to, and, in general, it is best to obtain a solution of zinc as free as possible from impurities. But a solution of zinc which has gone through the usual course of analysis is perfectly fit to be precipitated by phosphate of soda.

The ammoniacal solutions of zinc obtained with either class of blendes, after being carefully neutralised by hydrochloric acid, are precipitated by phosphate of soda, and zinc is estimated as before.

Sometimes either class of blendes contain small quantities of copper, but no notice should be taken of the presence of this metal, which, in this circumstance, is not precipitated with the zinc. However, if it existed in any quantity, it would be best to separate it first, by means of the copper reagent.* Now it just happens, and this is very fortunate, that nickel, cobalt, and manganese, which would trouble the estimation of zinc by this process, seldom, if ever, accompany zinc in blendes; but, should they exist in small quantities, their presence could be neglected, as they would remain in the solution. But this process must not be used in cases in which nickel, cobalt, and manganese, exist in any quantity, unless these three metals are first separated from the zinc.

Estimation of Zinc in Calamines.

Calamines are attacked by hydrochloric acid, and the mixture of gelatinous silica and of chlorides thus obtained being evaporated to dryness, re-acidulated by hydrochloric acid, diluted with water, and filtered, the filtrate can be submitted to two successive treatments with hydrochloric acid and ammonia, as in the case of blendes of the first class, and zinc estimated as in blendes. But, however carefully the operation is conducted, it is not possible to obtain a silica free from oxide of zinc, and it is by far the best to have recourse to the following process:—

Fifty grs. of the calamine are attacked in a platinum vessel, conveniently large, by a mixture of equal parts of hydrofluoric and hydrochloric acids. When the solution is completed, dilute sulphuric acid (half water and half sulphuric acid) is added in slight excess, and the mixture is slowly evaporated, until white fumes of sulphuric acid begin to come off. After cooling, water is added, and also a large excess of hydrochloric acid. The solution, which ought to be quite clear, is transferred to a flask, and there submitted to the two successive treatments described in the case of blendes of the first class, and zinc is estimated exactly as in that instance. Or the solution may be submitted to a regular analytical process.

When lime is present, it is advisable to separate it first by means of a little carbonate of ammonia. But, if magnesia exists, even in pretty large quantity, this substance is nicely separated from the zinc. It remains in the solution, in which it can be estimated as phosphate of magnesia and ammonia by addition of ammonia. However, if it existed in large proportion, it would be best to separate it, first by adding phosphate of soda to the ammoniacal solution of zinc; after the separation, zinc could be easily precipitated by neutralising the filtrate by hydrochloric acid.

These notes, however, apply much more to what might happen than to what actually occurs in most cases.

Estimation of Zinc in Brass.

The liquor from which copper has been separated by the copper reagent,† and resulting from the solution of 20 or 50 grs. of brass, is saturated at once, and without any previous preparation, by ammonia in excess, and this mixture neutralised by hydrochloric acid is precipitated by phosphate of soda and zinc estimated as stated. Or, better still, the liquor from which copper has been precipitated by the copper reagent, and resulting from the solution of 100 grs. of brass, is boiled to get rid of sulphurous acid, then submitted to sulphuretted hydrogen, whereby lead, arsenic, antimony, &c., are precipitated, then filtered, boiled once more to get rid of sulphuretted hydrogen, oxidised by nitric acid, saturated by ammonia, which precipitates small quantities of iron, filtered, and the filtrate neutralised by hydrochloric acid is precipitated by phosphate of soda.

* CHEMICAL NEWS, vol. xxiv., p. 91.

† *Ibid.*, p. 92.

As it is quite as easy to estimate large quantities of zinc as small ones by this method, the more zinc there is in a liquor the more accurate is the estimation of this metal.

Estimation of Zinc in German Silver.

This method cannot be applied to the estimation of zinc in this alloy unless nickel is separated immediately after copper, and zinc left alone in solution.

General Observations.

In the course of an estimation of zinc by this method, the chemist can depend on the result, whenever he can obtain the dense precipitate in the circumstances previously described; for whenever the substances which follow zinc in an ammoniacal solution exist in large proportions, the precipitate of phosphates remains bulky, and the dense precipitate cannot be obtained.

Cobalt, it is true, is precipitated freely along with the zinc, but, in this case, cobalt imparts a beautiful blue colour to the double phosphate, and reveals itself at once.

In the same circumstances, nickel would impart a greenish tinge to the precipitate.

I need scarcely remark that it is just as well to examine qualitatively the double phosphate with which zinc has been estimated. It should be free from lime, magnesia, nickel, cobalt, and manganese.

But all these observations will seldom find applications, and are introduced here only to meet possible but not actual cases.

When zinc forms only a small fraction of the substance analysed, the ordinary methods of separations ought to be, and generally must be, resorted to, but, when once isolated, zinc can be with advantage estimated as ammoniaco-zincic phosphate.

Such is, with all its advantages and all its imperfections, the method which I propose for the estimation of zinc. I hope that a happier hand will soon find a reagent volatile, if possible, or easy of separation with most substances, precipitating completely zinc in acidulated solutions of zinc and ammoniacal salts. Here is the problem; may the solution soon be discovered.

Analytical and Chemical Notes, Derived from the use of Phosphate of Soda in the above Process.

Estimation of Manganese.—If there was any difficulty about the estimation of manganese, or if excellent methods for the estimation of this metal were not as numerous as they are, I should publish a lengthy article on the following process, which can be safely recommended especially for the assays of manganese ores.

The hydrochloric solutions of manganese, freed from oxide of iron generally existing in them, by means of succinate of ammonia, are mixed with an excess of chloride of ammonium. An excess of phosphate of soda is added, and the mixture is heated to almost boiling-point. Manganese is precipitated completely in the state of phosphate of manganese and ammonia. This precipitate is well washed (it washes very easily) and dried at 100° C. Its formula is then $(\text{MnO})_2\text{NH}_4\text{O}, \text{PhO}_5 + 2\text{HO}$, and it contains exactly 29.78 per cent of manganese.

The chief advantage of this mode of estimating manganese over the usual method is that it is estimated in one series of operations, while by the ordinary process it requires two.

This process is as nearly as possible identical with the above process proposed for the estimation of zinc, and nearly all I have said in the former pages I could repeat here.

Ammonio-Phosphates.—Most of the neutral solution of oxides soluble in ammonia, mixed with an excess of chloride of ammonium, are precipitated by phosphate of soda, and when the mixture is boiled most of the ammonio-phosphates crystallise. Some of them are very remarkable. The phosphate of manganese and ammonia thus prepared (the double phosphate of the above process of

estimating manganese) forms crystalline scales, of a silky appearance, soft to the touch, and of a beautiful flesh-colour.

The phosphate of ammonia and cobalt forms beautiful crystals of an indifferent pink colour, but when this substance is calcined at a low temperature, phosphate of cobalt of an admirable deep blue colour is obtained; it preserves the shape of the original crystals, and forms a beautiful substance pseudo-crystallised.

A beautiful series of blues can be obtained by precipitating, by phosphate of soda, chloride of zinc mixed with chloride of ammonium, and containing variable quantities of chloride of cobalt.

The phosphate of ammonia and protoxide of iron is precipitated in the same general conditions, in the form of silky crystalline scales, very soft to the touch, and which possess a most remarkable appearance. Their colour, which I cannot very well describe, is analogous to that of certain greenish micas, and altogether very strange.

Chloride of ammonium is the crystallising agent in the preparation of these salts, remarkable in so many respects.

ON RECENT INVESTIGATIONS AND APPLICATIONS OF EXPLOSIVE AGENTS.*

By F. A. ABEL, F.R.S., Treas. C.S.

(Concluded from p. 138).

THE discovery made in 1864, by Mr. Alfred Nobel, that the explosive force of nitro-glycerine can be fully developed without any strong confinement of the charge, through the agency of a detonation, appeared to give that substance so great and well-founded a claim to superiority over gun-cotton and other explosive agents, in connection with some of their applications, that the pre-eminence which this liquid enjoyed for a time as an explosive substance of quite exceptional properties almost equalled the dread of its dangerous character inspired by the succession of fearful accidents which inaugurated its employment on an extensive scale. Not long afterwards, however, it occurred to my assistant, Mr. E. O. Brown, to try whether compressed gun-cotton could not also be violently exploded in the open air, through the agency of a detonation, and a result was obtained quite similar to that furnished by nitro-glycerine. I was led by this observation to institute a systematic experimental inquiry, with a view of throwing light upon the nature and cause of the remarkable phenomena exhibited by these two bodies, and I soon found that *all* explosive compounds and mixtures, even down to gunpowder, are susceptible of violent explosion by means of a detonation, though the nature and force of the required detonation vary very considerably with different explosive substances. The results arrived at by a careful inquiry into the conditions to be fulfilled in determining the detonation in open air of these compounds and mixtures, and of the operating causes, physical and mechanical, which tend to modify the character of the phenomena produced upon their exposure to heat, concussion, &c., are detailed in the *Transactions of the Royal Society*—their present discussion is precluded by the great length which this lecture has attained. It may, however, be stated in general terms, that although the amount of mechanical force developed by the initiative detonation, and the suddenness of its operation, play most important parts in determining the violently sudden metamorphosis of the substance submitted to their influence, neither the severity nor suddenness of the blow or concussion, nor the heat developed by it, nor the peculiar nature or comparative instability of the particular explosive body operated upon, suffice individually or collectively to account for all the several phenomena of detonation; but

* A Lecture delivered to the Members of the British Association at Edinburgh, August, 1871.

that some yet unexplained peculiarity in the initiative concussion employed, and probably some physical relation or antagonism between it and the particular concussion produced by explosion of the substance operated upon must, in many instances, contribute to produce results, positive and negative, which can be satisfactorily explained by simple reference to the operation of mechanical force, and consequently of heat. In illustration of this it may be instructive to give two examples. The detonation of compressed gun-cotton is accomplished by the explosion of 0.32 grm. (5 grains) of confined mercuric fulminate, placed in contact with the mass, but it requires ten times that quantity of the violent explosive agent, chloride of nitrogen, also confined, to produce the same result. Again, the mechanical force exerted by the explosion of nitro-glycerine is fully equal to that developed by the mercuric fulminate, yet a quantity of nitro-glycerine, about seventy times greater than the minimum of the fulminate required to detonate compressed gun-cotton, fails, when exploded in contact with the latter, to produce any other result than the complete mechanical disintegration of the mass.

With regard to the general manner in which a detonation action determines the violent explosion or sudden chemical disintegration of such a substance as gun-cotton, the similarity of its operation to that of a blow is readily demonstrated by many and simple experiments, for a description of which I must refer to my paper presented to the Royal Society in 1869; one or two may, however, be mentioned which have been made with gun-cotton, and which probably illustrate the subject sufficiently for present purposes. The heat developed in a mass, when submitted to a blow, depends upon the resistance which its particles oppose (by reason of its rigidity or solidity) to the motion of the body striking it. Repeated blows may be required to explode a detonating substance placed in the form of loose powder upon an anvil; the force being, at first, in part expended in compressing the particles into a compact mass. When no longer free to move, the resistance they oppose to the force applied determines the sudden transformation of the latter into heat to a sufficient extent to bring about the detonation of the substance struck. If, in the case of gun-cotton, the force developed by a detonation, even of a powerful character, is allowed to operate upon the material in a loose flocculent condition, the latter is simply dispersed; again, if the gun-cotton be only lightly compressed, a much more powerful detonation is required for its explosion than if it be in a very compact condition; and if the mass of the highly compressed material be only very small, it cannot be detonated by the means which are successful with larger masses, unless special precautions be taken, by fixing it rigidly to the detonating fuse, to prevent its being dispersed by the force which the explosion of the latter exerts. These facts, when compared with the following experiments, demonstrate that the action of a detonation in developing the violent explosion of the substance upon which it is allowed to operate, is that of a very sudden blow given to some portion of a mass, the particles of which are in a condition to resist the motive or dispersive power of the mechanical force applied. A bullet from a Martini-Henry rifle was fired at a distance of about 50 yards, against a slab of compressed gun-cotton, 0.75 inch thick, and 3.75 inches in diameter (weighing 4 ounces), freely suspended in air by a string; the gun-cotton was simply perforated by the bullet. A similar result was several times obtained with slabs of gun-cotton of the same dimensions, and with others double the thickness. On making the experiment with a slab of three times the thickness, the gun-cotton was inflamed but not detonated by the impact of the bullet. The mass was, in this instance, of sufficient thickness to offer considerable resistance to the penetrative power of the bullet; the passage of the latter was, therefore, retarded to such an extent as to give rise to the heating of the opposing gun-cotton particles up to their inflaming

point. This experiment was repeated with the same result, but when a bullet was fired against a piece of compressed gun-cotton four times the thickness of that first employed, and weighing one pound, the result was detonation of the mass.

It need scarcely be stated that the detonation of a large quantity of an explosive body is accomplished by the initiative detonation of a very small portion of the mass; this is the case even if the material is arranged in the form of a train of considerable length, the detonating fuse being applied at one extremity. Rows of gun-cotton disks from 3 to 5 feet in length, with intervals of 0.5 inch and 1 inch between the individual masses, have been detonated in this way. There is, however, a limit to the distance to which a detonation will be transmitted along a row of spaced disks, the limit being determined by the particular weight of the masses employed; if it be exceeded, those masses which are at the farther extremity will be inflamed and scattered, instead of being detonated. A few preliminary experiments have been made with the view of determining, by means of the chronoscope, the rapidity with which detonation progresses along a row of gun-cotton disks. This will no doubt vary with the sizes of the masses; in an experiment with disks weighing 2 ounces each, placed in a row without intervals, it was found that the detonation extended to 3 feet in about 1-5000th part of a second.

Time will not permit of the discussion of many other points of scientific interest connected with the detonation of compressed gun-cotton and of other explosive agents, but it will probably prove interesting if a few illustrations are furnished, in conclusion, of the practical value of this mode of developing the force of explosive agents.

The necessity for confining gunpowder and other explosive materials in strong receptacles, for the purpose of developing their explosive force, is greatly reduced, and is, indeed, entirely dispensed with in the case of charges fired under water, when detonating fuses are used as the exploding agents. Thus, if a quantity of gunpowder which, when enclosed in a strong iron receptacle, will be completely exploded, producing a particular destructive effect when fired in the ordinary way, is confined in a thin glass vessel, or in a bag of waterproof material, the receptacle will be burst open upon the first ignition of the charge, and a large amount of the powder will be dispersed in the water; but if a detonating fuse be employed to fire the charge contained in the thin envelope, the powder will be completely exploded, the destructive effect produced being at least as great as that of the charge fired in the strong vessel by the ordinary method. This result is of very great importance, because, in employing submerged charges of gunpowder or other explosive agents for purposes of demolition, or as submarine mines for war-purposes, it is no longer necessary to use very strong and cumbersome receptacles for the purpose of obtaining the desired result; their strength need only be sufficient to insure the perfect exclusion by them of water from the charge at the depth of immersion at which it has been employed. In the recent demolition of the wreck of the "Golden Fleece," off Cardiff, by the Royal Engineers, large charges (500 lbs.) of gunpowder were simply enclosed in waterproof bags and exploded with detonating fuses. The results produced with these were quite equal to those obtained with similar charges enclosed in strong iron cases.

Masses of hard material, of great size or strength, such as blocks of hard rock, large iron castings, or thick bars of wrought-iron, may be broken up by simply placing upon one of their surfaces a comparatively small charge, quite unconfined, of compressed gun-cotton, or of a nitro-glycerine preparation, and exploding it by means of a detonating fuse. In such operations it is obvious that the destructive effect of the detonation will be increased by covering the charge to be exploded by sand or other material, which will act as tamping; but, in hurried operations, results may be obtained with either of the materials specified, by detonating them when freely exposed to air, which could not

have been produced by previously known modes of using explosive materials. The demolition of stockades, bridges, and other structures, which it may be desirable to destroy or render useless as expeditiously as possible, in the course of military operations, may also be effected with much greater ease, rapidity, and certainty, by the aid of detonation, than by the old method of operation; and the ease and safety with which compressed gun-cotton may be applied to these purposes has been demonstrated by numerous experiments instituted by the Royal Engineers. In mining and quarrying operations, the process of hard tamping which is indispensable in connection with the ordinary method of blasting, may be dispensed with by application of gun-cotton and of nitro-glycerine preparations, which are more readily exploded, with full destructive effect, by detonation, than other explosive materials at present known. A laborious and often very hazardous operation may thus be dispensed with.

For the hasty demolition of buildings, and of military work, such as casemates, magazines, or forts, the explosion by detonation affords most important facilities, reducing the difficulties, danger, and cost of such operation to a minimum. Some results obtained in this direction by the Royal Engineers with compressed gun-cotton may be quoted in illustration of this. It was desired to destroy a counterscarp gallery (forming part of the old works at Portsmouth), which was 250 feet long, and 7 feet wide. Its front wall was from 5 feet to 5 feet 9 inches thick, and was pierced with nineteen loopholes. It was roofed over by an arch 18 inches thick (from over which the earth had been removed), and its total internal height was 7 feet 4 inches. At either end there was an opening, closed by a wooden door, which was protected by an iron grating composed of one-inch bars, 4 inches apart. It was proposed to submit this counterscarp to a succession of small experiments, and, in the absence of any experience of the effects of gun-cotton applied in the interior of a building, it was decided to suspend 60 lbs. against the wall, under the haunch of the arch, placing them in three charges near one extremity of the gallery. The simultaneous detonation of these charges accomplished the destruction of about 140 feet of the gallery—about 114 feet being actually demolished. But this was only part of the damage produced. The violent concussion at the other end of the gallery, where the column of gas was checked in its escape, occasioned the destruction of about 80 feet of this part of the counterscarp, and the bars of the iron grating, by which the exit was closed, were bent and twisted into fantastic shapes, and hurled to a distance of about 60 yards. This long gallery was thus rendered entirely useless, and the greater part of it destroyed, by the detonation of 60 lbs. of compressed gun-cotton; and there is little doubt that, had the same quantity been lodged in the centre instead of at one end, the gallery would have been completely demolished.

Another illustration of the simple, rapid, and effectual manner in which the demolition of structures of great strength may be accomplished by the detonation of compressed gun-cotton, was furnished by the destruction of a Martello tower near Rye. This structure, of circular form, was built of brick, the wall being 12 feet thick on the sea side, and tapering to 7 feet 6 inches on the land side. It had two window openings, and one door opening, and its cubical contents were 7600 cubic feet. On the base-ment of this tower 200 lbs. of compressed gun-cotton were placed in three piles, freely exposed, which were arranged to be fired simultaneously. Their explosion caused the upper portion of the tower, with the roof, to rise gently a few feet in the air; the walls turned over, outwards, and the upper part subsided to the ground; the demolition of the tower being most complete, while not a brick was projected 50 yards from the spot. The entire operation was accomplished by two or three persons, within one hour of their appearing upon the ground. A second tower was subsequently demolished with 184 lbs. of gun-cotton, with similar results. It was calculated,

from existing data, that at least 1200 lbs. of gunpowder must have been employed to produce similar results.

In this sketch of the recent progress which has been made in the application of explosive substances, many points of interest and importance have unavoidably been passed over; sufficient, however, will have been said to show not only that the production and utilisation of these powerful agents of destruction, and these indispensable auxiliaries in the development of industrial resources, have been advanced in an unprecedented manner within the last few years, but also that very much remains to be learned regarding their nature and operation and the conditions to be fulfilled in their most efficient application in many important directions.

NOTES FROM THE INTERNATIONAL EXHIBITION OF 1871.

(Concluded from p. 142).

Who has not asked the question—What is ozokerit? Written on the knife-board of omnibuses—staring from street corners and hoardings, even on the back of one's programme at concert or the theatre, was ever present the one word—ozokerit. But the mystery has this some time been cleared up satisfactorily; the more so as the production of ozokerit appears to open an extensive industry in the view, that for India and other hot climates, a candle having a high melting-point, and manufactured at a lower price than wax, is an absolute necessity. Ozokerit in candle manufacture seems to be offering formidable competition to paraffin. It exists in considerable deposits in Galicia, Hungary, and in Russia. In the latter country crude candles were manufactured out of the native material for the use of the miners; but it is only within the last year that it has been successfully dealt with by Messrs. J. C. and J. Field, who exhibit a series of specimens (7465-67) of native ozokerit, of the refined material, of candles, and other products obtained from this remarkable mineral. Native ozokerit is of a waxy consistency and foliated structure, varying in colour from pale yellow to dark brown, with sometimes a green tinge, and containing 85.75 per cent of carbon, and 15.15 per cent of hydrogen. It also contains a natural oil (7465) applicable to illuminating purposes. For the manufacture of candles the mineral is first carefully distilled, the product being mixed with an oil and formed into cakes under powerful pressure. These cakes are treated with sulphuric acid to remove the last traces of oil, and the melted material washed and filtered through animal charcoal. Candles made from this pure ozokerit have a melting-point between 59° to 61° C., and greater illuminating power than any other candle known. Professor T. C. A. Brock, of Denmark (7526), exhibits some stearic acid, the result of a new process of manufacture; but no details are given.

We now come to the consideration of the metals and metallic preparations exhibited. Messrs. Winsor and Newton contribute (7562) a series of pigments of extraordinary beauty prepared from thallium. The specimens include several shades of yellow and orange-red prepared from thallium chromates by the wet way; and green colours, also constituted of thallium and chromium, with a dark brown, a sulphide of thallium. Mr. J. Johnson (7496) exhibits black, grey, brown, and yellow colours prepared by calcining shales at different degrees of heat. These pigments are intended for cheaply coating iron. Messrs. Johnson and Matthey (7495) contribute specimens of magnesium illustrative of the process of manufacture. Magnesium, though classed with the alkaline earths, more closely resembles zinc in its principal properties. Its chief use is as an illuminating agent for photographic or signalling purposes; for the former it is well adapted, the

light being rich in chemical rays. Messrs. Walker, Campbell, and Co. (7428) exhibit specimens of block-tin pipes encased in lead, intended for the conveyance of soft water, which acts corrosively upon lead pipes. This mode of protection is the invention of Mr. Haines. There are also exhibited specimens of lead pipes (7429) coated externally with tin to afford protection from corrosion when laid in damp earth. Mr. J. F. Allen exhibits (7414) a series of alloys of copper with different proportions of manganese, manufactured under his direction at the works of Messrs. Newton, Keats, and Co., of St. Helens. Bergmann appears to have been the first to produce alloys of copper and manganese in 1774, and he describes them as being extremely malleable and ductile. In 1823 numerous experiments were made in Berlin, and in 1826 there were sold, under the general name of "*Weisskupfer*" alloys of copper and zinc containing manganese. Erdmann analysed a teaspoon composed of this alloy, and obtained it from a firm who kept their process secret; it was found to consist of 57.1 per cent of copper, 23.2 of zinc, and 19.7 of manganese. Messrs. Evans and Askin appear to have been the first in this country to manufacture alloys of copper, zinc, and nickel with manganese; and in 1850 Dr. Percy and Mr. Higgin gave much attention to the subject. The difficulty of manufacture laid in the remelting of the alloys, in consequence of the tendency of the manganese to oxidise out; but Mr. J. F. Allen has succeeded in the production on a large scale with greater uniformity than hitherto, and, by dispensing with the use of plumbago crucibles, at a considerably reduced expense. The alloys are produced by heating mixtures of charcoal, cupric oxide, and manganese carbonate in a reverberatory furnace with small coal as fuel. A non-oxidising flame is obtained by employing Siemens's arrangement. The alloys exhibited contain 5 to 25 per cent of manganese. A copper-zinc alloy with 15 per cent of manganese, termed "manganoid," is proposed as a substitute for German silver. Spoons, &c., of this alloy are exhibited, as well as some very tough wire drawn from an alloy containing 23 to 25 per cent of manganese. Alloys of copper and tin with manganese are proposed by Mr. Allen as a gun-metal.

The British Seaweed Company exhibit a complete series (7425) of the products obtained by the distillation of seaweed at their two extensive works in the Hebrides. These works are lighted by the gas obtained from the seaweed. Mr. Stanford's method is of course that employed, and as illustrative of the extent to which it is now worked it may be stated that the following numbers represent the annual production of potassium-salts at the Company's factories:—Carbonate, 600 tons; bicarbonate, 30 tons; chlorate, 50 tons; iodide, 23 tons; and bromide, 12 tons. Besides these products and the illuminating gas, there remains the charcoal, in some instances an excellent substitute for animal charcoal. The cheapness of seaweed charcoal is much in favour of its employment as a deodoriser of offal of all kinds; and Mr. Stanford shows that it can be used in the place of earth in the dry-closet system with great advantage, especially in dealing profitably with the *excreta* of towns. Employing seaweed charcoal as the starting point, he submits the product of the dry closets to distillation, and re-applies the residual charcoal to deodorising purposes. Mr. Stanford exhibits (7547) tar, calcium acetate, ammonia, and ammonium salts, as the marketable products resulting from the distillation. Glasgow is the first to take up the system which has been worked out by Mr. Stanford with such great labour. Crease's "Patent Cleansable Tank Filter," exhibited by Messrs. Burney and Co. (7479), designed for use on board ship, embodies another efficient sanitary application of charcoal.

M. Ludwig Mond exhibits specimens (7513 and 7628) of the products of the utilisation of alkali waste. M. Mond brought his present process into practice in 1863, and it is now that adopted for recovering the sulphate in most of the German and in two of the largest French

works. The process consists in at once submitting the waste, in the same tanks in which the separation of alkali by lixiviation has been accomplished, to successive treatments with air, and lixiviations for the removal of the resulting soluble sulphur-compounds. After the soda-liquor has been drawn off from the residuum, air is made to penetrate the latter by being forced through perforations in the false bottom of the tank. The residue is then lixiviated, the extract or sulphur liquor containing principally calcium hyposulphite, bisulphide, sulphhydrate. When sufficiently concentrated, the liquor is mixed with chlorhydric acid to precipitate the sulphur, no sulphuretted hydrogen being evolved, because the liquor contains an excess of calcium hyposulphite. The precipitated sulphur is then transferred to iron vessels, in which it is melted by injected steam. M. Mond exhibits a diagram of the arrangement in actual use for extracting sulphur from 300 tons of alkali waste weekly. This exhibitor also contributes a model (7602) of a simple form of furnace, devised by MM. Helbig and Horsenclever, for effecting the roasting of ores by a continuous operation, which is accomplished through the agency of an inclined plane, or of several such planes, inclosed in the furnace. These planes are fixed at the natural angle presented by the sides of a heap of ore, which descends gradually and regularly as the material is removed from the bottom of the furnace. These furnaces are especially adapted for the roasting of small ore, and are now advantageously employed for this purpose in many German works. In some cases they are connected with the roasting furnaces for pyrites and blende, so that the heated gases from these are passed into the sloping furnaces, assisting in the heating.

Few of the inventions are of greater practical importance than the "selenitic mortar" (7519) exhibited by Col. H. Y. D. Scott, C.B., R.E. Some sixteen years ago Col. Scott first noticed the influence of a small proportion of calcium sulphate, or the sulphuric acid it contained, upon the setting qualities of inferior limes. It was found that by intimately mixing as little as 5 per cent of plaster-of-paris with freshly-burned fat lime, the heating upon the addition of water was prevented, and the product hardened after a time. The sulphuric acid or calcium sulphate is first mixed with the water to be used in making the plaster or mortar; the lime is then added, and the whole ground to a creamy paste, which is mixed with the requisite proportion of sand for the production of a mortar or plaster. Five or six parts of sand may be used to one of lime for producing rough plaster or mortar, being nearly double the proportion employed in the ordinary method of mortar-making, when the lime is allowed to slake. The saving is therefore very considerable. Mr. G. R. Redgrave (7520) exhibits a form of mill adapted to the rapid preparation of selenitic mortar. The only other cement exhibited is a specimen of Portland by Mr. Wedekind (7559) obtained by a new process from Hofmann's kiln; but there are no details afforded.

In the Chemical Stoneware Department Mr. Bailey and Messrs. Doulton and Co. are the only contributors of any importance. Mr. Bailey exhibits some large acid tanks, receivers, condensing worms, and other vessels. Messrs. Doulton and Co. have the finest collection of chemical ware, among which are two acid force-pumps of very superior finish. This firm also excels in the fire-clay department, to which they contribute an enormous plumbago crucible, free from flaws, nearly 6 feet in height, and 4 feet in diameter at the mouth; it is asserted to be capable of melting more than 13,000 lbs. of metal. There is also shown a fine collection of muffles for glass-staining and other purposes. The Patent Plumbago Crucible Company also exhibit a most valuable and interesting assortment of crucibles, assay pots, &c.

The conclusion must now be drawn, for we have considered nearly all the chemical products exhibited, and it will be seen that certainly the results of this year's exhibition must be judged not by the number, but by the intrinsic worth of the inventions.

CORRESPONDENCE.

ALUM IN BREAD.

To the Editor of the Chemical News.

SIR,—I had occasion some few months since to determine the purity of a number of samples of bread, and among other experiments was used the test mentioned by Dr. Moffat in his Glasgow Lecture, and referred to by Mr. Horsley in your last issue.

Some of the specimens gave a purple colour very quickly, but the majority gave a fine blue, several of them within a little time after application of the solution, whilst in others the colour only became developed after an interval of several hours, or on standing over night.

Experimental specimens of flour and of bread, to which alum had been purposely added, gave in each case a purple colour.

I am quite unable to assign any practical value at present to these results, for I have not further examined them. It may, however, be as well to note that all the blue specimens contained potatoes, and that a drop or two of logwood solution gave a blue colour to the ordinary water of the town, which contains a trace of iron, and to this also, possibly to the earthy salts; I presume the change of colour in the water is due; whether any similar influence is exercised by the test over water and salts in the loaf I am unable to state.

So far as my personal knowledge goes, these logwood tests for determining the presence or absence of alum in bread and flour are by no means quite satisfactory.—I am, &c.

RICHARD WEAVER.

Leicester, Sept. 20, 1871.

RING VORTICES IN WATER.

To the Editor of the Chemical News.

SIR,—In the note I addressed to you on the 5th of August last, as a postscript to my paper on the above subject, which was published in your issue of the 4th of August last, I referred to the previous labours of Mr. Charles Tomlinson, as described by him in the *Philosophical Magazine* for 1864. Mr. Tomlinson in those papers refers to the still earlier labours of Professor W. B. Rogers, of Boston, U.S., as described by him in the *American Journal of Science* for September, 1858. After some trouble, I have procured a copy of this journal, and it is now before me. Professor Rogers has done so much, and that so well, as regards these rings themselves, that I venture to ask you to reproduce some of his remarks and figures.

He does not allude to the secondary rings or discs, nor to the currents caused by the passage of the rings through

FIG. 1.

the fluid, and as these secondary phenomena, i.e., the "tendency to form from merely straight currents structures at intervals in planes at right angles to the currents," have been suggested by me as probably throwing light on the formation of clouds in strata, I have also to ask you to reproduce

a communication from a friend, with whom I have often discussed the question as to why clouds floated in strata, who is conversant with many of the effects of cloud perspective, and who saw, I think, in actual progress, the phenomenon of a stratum of cloud giving out a column or

current, and the conversion of that current into another stratum. My friend's communication was written to me before he had heard of any of the experiments now noticed. At our last discussion on cloud strata he had related this circumstance to me, and when I saw the rings and their sequels, his account at once came to my remembrance, and, without telling him for what purpose I required it, I asked him to put in writing his recollection of the facts. Professor Rogers' most characteristic sketches are, I think, the following:—

Fig. 2.

Fig. 1, the commencement of a smoke ring, and Fig. 2 the section of "a continuous and moderate blast." He gives no drawings of liquid rings, but describes very suitable apparatus for their production, and traces most clearly the resemblance between the two classes of phenomena. The remarks of his to which I attach most force are perhaps the following, but it is not an easy task to avoid much fuller quotations. Speaking of smoke rings, "we observe the ring to be made up of a coil of cloudy air—between the folds of which is rolled up a similar coil of transparent atmosphere," Fig. 1. Referring to his figure reproduced in Fig. 2, "They (the regular alternations) at least furnish conclusive proof that even a large stream of gas discharged under steady pressure does not flow with continuous uniformity, but becomes the seat of periodical movements at equally recurring intervals." Speaking of a liquid ring. "It is thus identical with the rotation of a gas ring impelled in a descending direction." "The liquid ring, moreover, resembles that of gas in being composed of a coil of coloured fluid enfolding a parallel uncoloured coil." Too long for extract is the account of Professor Rogers's experiments in producing smoke rings from soap bubbles filled with smoke by piercing the bubble in various positions, and expelling its contents through this opening by means of the contraction of the bubble film. In fine, simply regarding the experimental formation of the rings, Professor Rogers has left little undone. Mr. Charles Tomlinson has shown that various effects result when dissimilar liquids are used. I have tried to show the alliance of this kind of phenomena to all cases of fluids in motion, when one part of the mass moves with a different velocity to the rest. To this mode of motion I attribute many chemical results now attributed to "diffusion." If chemists will repeat these experiments and consider what must happen when fluids are acting on each other, I think (at all events amongst technical chemists, the body to which I belong), "diffusion" will diminish in importance and mechanical action, i.e., mode of motion will take its place.

I annex my friend's letter.—I am, &c.,

HENRY DEACON.

Widnes, September 4, 1871.

Copy of Letter from Mr. Samuel Hall to Mr. Henry Deacon.

"41, Barnsbury Street, London, N.

"August 1, 1871.

"It was about this time of year 1869 that I saw the cloud in the act of transferring itself from one strata of

the air to a higher one. The centre of the cloud was about two or three miles north of Lausanne, on the Lake of Geneva, no mountains sufficiently near to interfere with the process. Time about 11 a.m., a fine day, with a few clouds, which eventually disappeared. The cloud particularly noticed was a cumulo-stratus, say, two or three miles long, and floating from 3000 to 4000 feet above the surface of the ground. When first seen there was a kind of pillar of cloud rising rapidly from the centre of the mass. This took my attention, and I observed it for a few minutes. The pillar seemed to stop rising almost immediately after I commenced looking, and there accumulated a denser head, which began spreading itself out horizontally.

"Unfortunately, owing to the direction of our walk, our backs were turned to the cloud, and my companion

was not particularly interested in it. However, from time to time I turned and watched it till in about half an hour I should think, but am uncertain with regard to this, it had assumed the shape of a dumb-bell with very flattened heads, at least half the cloud having attained the higher level, which I should very roughly estimate at another 4000 feet.

"I will just add that, although there was no mem. taken at the time, I have no doubt of the general accuracy of this description; also that perspective could not have deceived me very much. Though looked for, I could not detect any twisting motion in the ascending pillar."

"(Signed) SAMUEL HALL."

"The accompanying are rough sketches of first and last appearance.

Fig. 3. (As first seen).

Fig. 4. (As last seen).

MAGNETIC MOTIVE POWER.

To the Editor of the Chemical News.

SIR,—In the postscript to my letter last week, by some clerical or other error, the numbers were given incorrectly. I intended to write that 1,199,700 foot-pounds of work were produced by 7 ounces (avoirdupois) of iron.

It may be satisfactory to describe how the figures were obtained. Two electro-magnets fixed on an axle were made by commutators to rotate in front of a fixed electro-magnet. Revolving fans were placed on the axis, which, by the resistance of the air, reduced the speed to an average of 93 revolutions a minute. When the electrical current was cut off, it was found that a weight of 86 pounds fastened by a cord to an axle one inch in diameter, produced and sustained the same rate of revolution; in ten hours, seven ounces of iron were consumed, so that my calculations were purposely kept below the mark in order to be on the safe side.

The result was verified and confirmed by making the negative power, when the fans were removed, raise at the same rate of revolution six pounds fastened by a cord to an axle of one foot diameter, in addition to the friction.

The potential of the battery was about $\frac{1}{10}$ ths that of a Grove. Joule calculates the utmost possible force of a grain of zinc in a Grove battery at 267 foot-pounds, and the utmost practicable, half that, or 134 foot-pounds. Here the work of a grain of iron was at least 388 foot-pounds, and any one acquainted with the subject must see that with this primitive apparatus only a small part of the power of the current could be utilised.

Mr. Slater encouraged and convinced by the result, is now engaged in the construction of a larger engine, fitted for practical work, and made in a more workmanlike and scientific manner, with numerous magnets instead of only three. Having spent a large part of his life, and hundreds, or even thousands, of pounds in experimenting on the best construction of magnets and best methods of

utilising electric power, he has at last attained a result which is practically most important. His practical acumen and experience always convinced him of the error of Joule's views, and proved to him that there was sufficient power resident in electro-magnets to make an economical motive power, if he could but devise a means of getting it out.—I am, &c.,

2, The Cedars, Putney,
Sept. 25, 1871.

II. HIGHTON.

VALENCY OR ATOMICITY.

To the Editor of the Chemical News.

SIR,—There is perhaps no doctrine of modern chemistry that has been more fully examined or discussed than "Valency" or "Atomicity," and yet it must be admitted that the proper rank of several important elements in the scale of equivalency is still undetermined.

If we take, for example, nitrogen, N, we find that in ammonia, H_3N , it is trivalent, although in nitric oxide, NO, it is divalent, corresponding to O, which is usually regarded as a dyad.

Then again, carbon, C, in carbonic acid, CO_2 , is tetravalent, although in carbonic oxide, CO, it is divalent, assuming, as before, that O has invariably the same valency.

My chief object, however, in this brief communication, is to draw attention to iron, Fe, which is ranked, I believe, by all chemical writers as a divalent element. And if the protoxide, FeO , be taken, the Fe must certainly be viewed as divalent, provided the oxygen with which it is combined be O. But if instead of FeO , we select the sesquioxide, Fe_2O_3 , we find that the Fe ought to be trivalent to correspond to O.

If we glance, too, at the simple chemical equation—

we find the Fe_2 taking the place of 6H, and consequently the Fe appears, as in the instance of Fe_2O_3 , to be a triad rather than a dyad.

As another anomalous example, I would just refer to the bisulphide, FeS_2 , for in this compound we have to regard the metal as tetravalent, if S be divalent or S'.

What, then, is the true quantivalence of Fe, and how can it be definitely determined?

This important enquiry I beg to submit to your numerous scientific readers.—I am &c.,

W. H. O.

Mildmay Road, Stoke Newington,
Sept. 20, 1871.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 2^e, 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

Action of Chlorine upon Aldehyde.—A. Wurtz.—Since MM. Krämer and Pinner (*Deutsche Chem. Gesellsch. Berlin*, 1870, p. 383) had contested the accuracy of the author's experiments on the above-named subject (published in the *Annales de Chimie et de Physique*, 3rd series, vol. xlix., p. 58), the author has repeated his former experiments. As before, he has found that there is formed chloride of acetyl and a product, $\text{C}_2\text{H}_3\text{ClO}_2$, boiling at 120° , being the same as that which Maxwell Simpson has found by directly combining aldehyde with chloride of acetyl; although there is no doubt whatever concerning the formation of chloride of acetyl as a product of the action of chlorine

upon aldehyde—mixed, however, with perchloride of carbon, in order to lessen the violence of the reaction—there are other by-products formed, of a high boiling-point, which, excepting the compound $\text{C}_2\text{H}_3\text{ClO}_2$, have not been further studied; the constitutional formula of that compound is either—

This compound is decomposed by water, and the manner of its decomposition proves that the formula assigned to this body, by the German savants above-named, is not correct—viz., $\text{CH}_3\text{ClCOH} + \text{CH}_3\text{COH}$.

Essay on the Use of Divers Alloys, and more especially of Phosphorus-Bronze, for the Casting of Pieces of Ordnance and other Purposes.—Montefiore-Lévi and Kinzel.—This paper is a lengthy abstract from a work published by the authors, and containing the detailed account of an extensive series of experiments made on the large scale on the preparation of various alloys of copper and tin, and the effect produced thereon by the addition of phosphorus in small quantity. It appears, on the whole, that the addition of the element just named is of great value in producing alloys possessed of excellent properties, especially for the manufacture of bronze guns. The Academy has appointed a committee of six of its members, among them MM. Dumas and Frémy, to study this important matter, and report thereon.

Although not belonging to the subjects usually treated of in this periodical, we quote the following paper:—

Note on Geographical Researches Made in the Island of Madagascar during the Years 1865-70.—A. Granddidier.—A very important contribution to the physical geography of an island which appears to have been thoroughly surveyed by the author.

Aëronautic Journey of the Volta Air-Balloon, undertaken on December 2, 1870, for the purpose of a Scientific Mission.—J. Janssen.—This paper contains the very minutely-described account of the author's balloon journey from Paris to Briche-Blanc, Commune de Beuvron, Loire Inférieure, not far from Saint-Nazaire, whence the traveller proceeded by rail to Tours and, *via* Bordeaux, to Marseilles, and, farther, by steamer, to Oran, for observation of the last eclipse of the sun. It appears that during this journey several photographs of places and localities over which the balloon passed were taken with great success, so that this mode of obtaining maps of towns and country is at present being experimented on by M. Nadar.

Spectrum Exhibited by Sulphur.—G. Salet.—Notwithstanding the high scientific value of this paper, its contents, including a series of tabulated results, are not suited for abstraction.

Subchloride and Oxychlorides of Silicon.—L. Troost and P. Hautefeuille.—This very lengthy memoir treats, in the first place, on the preparation of the subchloride of silicon, by passing a rapid and continuous current of chlorine gas over silicon at a very high temperature—up to the point of rendering porcelain tubes as soft as wax, a heat at which malleable iron fuses readily,—care being taken to arrange the apparatus in such a manner as to cause the vapours to pass repeatedly over the silicon. The crude product, having been purified, yields the sesqui- or subchloride of silicon in the shape of a very mobile colourless liquid; sp. gr., at $0^\circ = 1.58$; at -14° , this liquid freezes, and is then very similar to boric acid; at 146° , the liquid boils; its vapour density at $239^\circ = 9.7$; heated in contact with air, the vapour of this body inflames spontaneously. This substance is curiously enough, only stable at temperatures below 350° or above 1000° , but is dissociated very rapidly, especially at temperatures between 440° and 800° ; the formula of this body is Si_2Cl_3 . Protochloride of silicon is also a liquid, of which the boiling-point, density, and vapour density are difficultly ascertained, on account of its retaining oxychlorides of silicon. Of these last-named bodies, the authors have found no less than five, having all a different composition:—The first is a liquid, boiling at from 152° to 154° ; formula, $\text{Si}_4\text{O}_3\text{Cl}_2$. The second, also a liquid, boils at 200° ; vapour density, 15.9 ; formula, $\text{Si}_4\text{O}_3\text{Cl}_2$. The third, a liquid, boiling at 300° ; centesimal formula, $\text{Si}_4\text{O}_3\text{Cl}_2$; formula, deduced from vapour density $= 28.2$, $\text{Si}_{11}\text{O}_{20}\text{Cl}_{12}$. The fourth, an oily liquid, which becomes pasty at below 0° , and boils at 400° ; formula, $\text{Si}_4\text{O}_3\text{Cl}_2$. The fifth, a solid body, not fused at 440° , soluble in the preceding bodies; formula, $\text{Si}_4\text{O}_3\text{Cl}_2$. The last portion of this memoir treats on the oxychlorides of boron, titanium, and zirconium.

On Nitro-Ethyl, Nitro-Glycol, and the General Method of Converting Alcohols into Corresponding Nitric Ethers.—P. Champion.—Nitro-ethyl is formed by the action of nitro-sulphuric acid upon previously-pulverised ethal gradually introduced into the acid liquid; the product is purified by dissolving it in ether, and washing this solution with water. Nitro-ethyl is a liquid, soluble in ether, but hardly so in alcohol and water; at between 10° and 12° , it becomes solid and crystalline; the sp. gr. of the liquid $= 0.91$; its formula is $\text{C}_2\text{H}_5\text{NO}_2$. A high temperature decomposes this substance, a carbonaceous residue being left. When put upon a piece of very hot sheet-iron, nitro-ethyl takes fire, assumes at the same time the spheroidal state, and burns off with a sooty flame. Nitro-glycol is prepared by the action of nitro-sulphuric acid upon glycol in the same manner as nitro-glycerine. The former-named body is a fluid, sp. gr. $= 1.48$, insoluble in water, very soluble in alcohol and ether, and detonating violently by percussion but not by the action of a high

temperatures. Nitro-glycol is poisonous, and exhibits, when taken internally, symptoms akin to those produced by nitro-glycerine. By careful manipulation, and especially by applying lower temperatures to the acid mixture alluded to, the author has been enabled to prepare, from a series of alcohols, nitric ethers.

Journal für Praktische Chemie, Nos. 11 and 12 (double number), 1871.

The following original papers are contained in this number:—

Contribution to our Knowledge of Hyponitric Acid and Nitrous Acid.—Dr. C. W. Hasenbach.—The leading points of this exhaustive essay, illustrated by woodcuts, may be summarised as follows:—Nylander's idea, that a peculiar and isomeric hyponitric acid is formed when arsenious acid is oxidised by the aid of nitric acid (sp. gr., 1.33), is not correct, the fact being that either a mixture of nitrous and hyponitric acids, or the latter only, is formed, this being dependent upon the degree of concentration of the nitric acid employed. Hyponitric acid and deutoxide of nitrogen combine together at a high temperature, forming chemically pure nitric acid; hyponitric acid and chlorine yield, under similar conditions, the chloride of nitric acid; bromide of nitric acid cannot thus be obtained in pure state, since the combination is destroyed by boiling; iodine and hyponitric acid do not combine at a high temperature; cyanogen and hyponitric acid form at a high temperature a most violently explosive compound, probably the cyanide of nitric acid; the compounds of hyponitric acid with chlorine, bromine, and cyanogen are not formed at all, or only to a very limited extent, at a lower temperature: nitrous acid and oxygen combine even at the ordinary temperature of the atmosphere, forming hyponitric acid; carbonic oxide and sulphurous acid combine at a comparatively low temperature, forming compounds which have not been further investigated; benzol is not directly nitrated by hyponitric acid unless aided by sulphuric acid, in which case nitrobenzol is formed. The author prepares hyponitric acid in large quantity by treating nitric acid (sp. gr., from 1.38 to 1.40) with small lumps of arsenious acid of the size of peas, heat being applied and a good condenser. Through the dark green coloured liquid collected in the receiver (a mixture of nitrous and hyponitric acids) a current of oxygen or atmospheric air is passed, in order to convert the nitrous acid into hyponitric acid, after which the liquid is rectified by carefully conducted distillation. The molecular formula of liquid hyponitric acid is—

but that of the vapour above 100° is NO_2 .

On Sulphur Compounds.—Dr. E. Drechsel.—Owing to the large number and complexity of the formulae required for the due understanding of the contents of this valuable essay, it is not well suited for abstraction.

Conversion of Formic Acid into Methyl Alcohol.—A. Lieben and A. Rossi.—From formate of lime, formylic aldehyde was obtained by distillation; the crude product of this operation was rectified, and treated with sodium amalgam, and then again submitted to fractional distillation. The liquid resulting from that operation, being treated with caustic potassa, yielded a fluid which was by further rectification found to be identical in every respect with methyl alcohol; 250 grms. of formate of lime yielded about 4 grms. of the alcohol.

On Monobenzyl-Urea.—S. Canizzaro.—Among the products of the reaction between benzylic chloride and cyanide of potassium, the author found, in addition to dibenzyl-urea (a solid body), also another compound, which is rather soluble in water and alcohol, but best in ether. This substance is, in the pure state, a solid crystalline body, fusing at 147°; heated to 200°, ammonia is given off, and dibenzyl-urea. The formula of the monobenzyl-urea is—

Preliminary Notice on a New Method for Forming Hydrocarbons.—F. Pfankuch.

On Sulpho- and Cyaniform.—F. Pfankuch.—By causing sulphur to act upon iodoform contained in a sealed tube, the author has obtained a compound, $\text{C}_2\text{H}_2\text{S}_2$. By experimenting with iodoform and mercuric cyanide, the author obtained a body which is to be considered as the double salt of cyaniform with iodide of mercury; formula—

On Sulphur Ethyls.—M. Müller.—Preliminary notice.

Gases Occluded in Coal.—E. Meyer.—Preliminary notice; reserved for full translation.

Action of the Hydracids upon the Alkaloids of the Cinchona Group.—W. Zorn.—Preliminary notice.

Products Obtained by the Electrolysis of Acetate of Potassa.—Drs. T. Kempf and H. Kolbe.—Twenty-two years ago, Dr. Kolbe proved that the chief products of the electrolysis of a concentrated solution of acetate of potassa were carbonic acid and methyl-gas; resuming these experiments, the authors now find that, by the process alluded to, also ethylene, acetate, formiate, and carbonate of methyl are formed, and a substance which as yet has not been further investigated.

Action of Ethylene Iodide upon Acetylides of Copper.—E. Carstanjen and A. Schertel.—Preliminary notice; a remark which also applies to the following, as well as to some of the foregoing, papers, all of which are published only in a fragmentary form, the researches they communicate being temporarily discontinued on account of the holidays.

Experiments Made with the View to Prepare a Carbonic Oxide Cyanide, $\text{CO}(\text{CN})_2$.—E. Carstanjen and A. Schertel.

Oxidation of the Naphtyl-Carbonic Acid, $\text{C}_{10}\text{H}_7\text{COOH}$.—E. Carstanjen and A. Schertel.

Synthesis by Nascent Formic Acid.—E. Carstanjen and A. Schertel.

On Chloracetone and Cyanacetone.—L. Glutz and E. Fischer.

On Simple Chlorinated Chloretethyl.—W. Wulsters.

On some Chromium Compounds.—J. Heintze.

Action of Potassium Sulphhydrate upon Chlorbenzoyl.—A. Weddige.

New Derivatives from Chloride of Carbon.—K. Ifsch and H. Kolbe.

Decomposition of Grape Sugar by Oxide of Copper in Alkaline Solution.—A. Claus.—We regret that the length of this highly valuable monograph prevents any other quotation than the title.

Zeitschrift für Chemie von Beilstein, No. 9, 1871.

This number contains the following original papers and memoirs:—

Contribution to our Knowledge on the Quintanes (Quintane).—M. Lwow.—This paper records some experiments made with the view of obtaining by synthesis a normal quintane—

Normal iodobutyl and zinc methyl were found not to react upon each other even at a high temperature, but the tertiary iodobutyl, $\text{C}(\text{CH}_3)_3\text{I}$, acts upon zinc methyl at the ordinary temperature; the main result of this reaction was found to be a fluid lighter than water, and of a high boiling-point (polybutylene). The result of the reaction of iodomethylene and zinc ethyl was— $2\text{Zn}(\text{C}_2\text{H}_5)_2 + 2\text{CH}_2\text{I}_2 = 2(\text{C}_2\text{H}_5)_2 + \text{C}_2\text{H}_4 + 2\text{ZnI}_2$.

Preparation of Methylene Iodide.—J. Bijnudocho.—This paper treats on the most advantageous method, and the best proportions, of preparing methylene iodide by the reaction of HI upon chloroform. The result obtained is that the best proportion corresponds to the formula $\text{CHCl}_3 + 4\text{HI} = 5$ grms. of chloroform to 40 grms. of hydriodic acid, the mixture being heated for twenty-four hours to 130° in a sealed tube.

Miscellaneous Researches.—A. Engelhardt and P. Latschinow.—This lengthy essay is divided into the following sections:—Diphenyl bodies; preparation of diphenyl; diphenyl-sulpho-acid; diphenyl-disulpho-acid; bromated a thymol-sulpho-acid; binitro-thymol from a thymol-sulpho-acid; oxidation of thymol; bromated para-cressol-sulpho-acid; chrysianisic acid; binitro-phthalic acid.

Structure of Chlor-Iod-Propylene.—W. Sorokin.—This paper is not suited for useful abstraction, as it requires a large number of complex formulae; an observation which also applies to the two following papers:—

Structure of Ethylene.—W. Kriwaxin.

So-Called Dichloracetone.—W. Kriwaxin.

Decomposition of Ethylene Bromide by Water.—W. Kriwaxin.—This paper contains the results of some experiments made with the view to prove that Carius's experiments (*Ann. Chem. Phys.*, cxxx., 172), according to which $\text{C}_2\text{H}_4\text{Br}_2$ and H_2O yield, at from 150° to 160°, aldehyde and HBr, are wrong, since the substance taken by him for aldehyde-ammonia is only bromide of ammonium.

Hydrocarbon, C_7H_{14} , and its Derivatives.—W. Markownikow.—The hydrocarbon alluded to has at 14° a sp. gr. of 0.6985; vapour density, 3.387; colourless, very mobile fluid. Pseudo-heptylen (C_7H_{14}) combines readily with iodine and bromine, but the bromide ($\text{C}_7\text{H}_{13}\text{Br}$) is decomposed by water at 100°, yielding some pseudo-heptyl-alcohol, a fluid which exhibits a camphor-like smell, is not solidified at -20°, and by many of its reactions is split up into C_7H_{14} and H_2O .

Preliminary Communication on the Products of Oxidation of Dichlorhydrine.—W. Markownikow.—By treating a pure dichlorhydrine, boiling at a fixed temperature, with an oxidising mixture ($\text{K}_2\text{Cr}_2\text{O}_7$ and H_2SO_4), the author obtained a substance which formed with bisulphite of soda a solid crystalline compound— $\text{C}_2\text{H}_4\text{Cl}_2\text{O}_5\text{S}_2\text{HNa}$.

Dichloracetone has been consequently formed, and the formula of dichlorhydrin is, therefore, $\text{CH}_2\text{Cl}-\text{CH}(\text{OH})-\text{CH}_2\text{Cl}$.

On some of the Derivatives of Ortho-Toluidine.—E. Wroblevsky.—This essay contains the following sections:—Tribrom-ortho-toluidine; tribrom-toluidine; dibrom-aceto-ortho-toluidine; dibrom-toluidine; dibrom-toluidine; nitro-dibrom-toluidine.

Properties of Trimethyl-Carbinol.—A. Butlerow.—Perfectly anhydrous trimethyl-carbinol is a solid body, rhombo-prismatic crystalline, fuses at 25°, attracts water and dissolves therein, boils at 82.5°; sp. gr., at 30°=0.7788, at 0°=0.8075. Trimethyl-carbinol hydrate, $2\text{C}_3\text{H}_9\text{O} + \text{H}_2\text{O}$, is fluid at 0°, boils at 80°; sp. gr., at 0°=0.827.

Triethyl-Carbinol.—A. Nahapetian.—The substance just named, prepared from propionic acid chloride and zinc ethyl, is fluid even at -20°, has a camphor-like smell, and is almost insoluble in water; sp. gr., at 0°=0.8593.

Dimethyl-Pseudo-Propyl-Carbinol.—J. Prianchnikow.—The body just mentioned is a fluid boiling at 112° to 113°, soluble in water, freezes at -35°; sp. gr., at 0°=0.8364; by oxidation, it yields acetone and some acetic acid.

On a New Amylen.—M. Ermolaen.—The iodide of dimethyl-ethyl-carbinol yields, when decomposed with alcoholic solution of caustic potassa, the amylen here alluded to, according to the following formula, the reaction requiring no heat and separation of a fluid:—

The amylen combines with bromine.

Platin Cyanide and Tartrates of Glucinum.—F. Toczynski.—This exhaustive memoir is divided into the following sections:—On glucina and its reactions; cyanogen compounds of glucinum; tartrates of glucinum.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, June, 1871.

This number contains no original papers relating to chemistry or allied sciences.

Les Mondes, August 31, 1871.

Among the original matter contained in this number we notice the following:—

Sand and Clay.—Dr. Choyer.—A lengthy but interesting geological essay.

Conduction of Heat.—Rev. Laborde.—This paper treats on some phenomena observed by the author while directing a blowpipe flame on the surface, as well as on jets of water; and on some practically useful conclusions to be deduced from his experiments.

Pressure Exerted by the Gases Generated by the Explosion of Gunpowder.—Captain Noble.—A very important essay on this subject; also containing a good account of the various labours of different authors who, since De la Hire (1702) first sought to explain the action of gunpowder, have treated on this subject up to the present day.

American Journal of Pharmacy, September, 1871.

The original papers contained in this number only bear upon subjects specially relating to pharmacy and pharmacognosy.

La Revue des Scientifiques de la France et de l'Etranger, September 9, 1871.

This number does not contain any original papers relating to chemistry or allied sciences.

NOTES AND QUERIES.

Soda from Cryolite.—(Reply to W. F. Catcheside.)—The process is very completely and accurately described, and if you work carefully you will certainly be able to obtain the results precisely as stated; supposing any cryolite to be imported, it is more likely to find its way to either Liverpool, Glasgow, or Newcastle-upon-Tyne than to London.

Test for Nitric Acid.—(Reply to "Chemicus.")—Take a freshly-made cold saturated solution of pure sulphate of iron in distilled water, and pour some of this solution into a test-glass, and add slowly an equal bulk of the sulphuric acid to be tested for nitrous compounds, taking care to let the acid flow slowly and gradually along the side of the glass into the sulphate of iron solution. After having been left standing for some time (a few hours at least) there ought not to appear between the two layers of the fluids a brownish coloured film; if such appears, the sulphuric acid is contaminated with nitrous compounds. Sulphate of aniline—made *extempore* by adding five drops of aniline to 25 c.c. of pure dilute sulphuric acid (sp. gr. = 1.113 to 1.117 = 13 per cent strong acid), and stirring the two liquids until the solution is complete—is cautiously added in a quantity of $\frac{1}{4}$ c.c. to 1 c.c. of the sulphuric acid to be tested; if the latter contains even a slight trace of nitric acid, a rose red-coloured layer will make its appearance between the fluids.

TO CORRESPONDENTS.

M. P. S.—Gessner's work on "Coal-Tar Products" will probably answer your purpose.

R.—Consult Watts' "Dictionary of Chemistry."

T. W.—This correspondent wishes to know—(1) Extent and price of Dr. Gladstone's lecture on "Theology and Natural Science." (2) Where Dr. Moffat's lecture on "Alum in Bread" is published. (3) If Dr. Frankland's "Lecture Notes" vol. ii. (Organic Chemistry), is published yet.

A. Keiffenheim and Co.—We will supply the information next week.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

ANALYTICAL LABORATORY and SCHOOL of TECHNICAL CHEMISTRY.

7 and 9, HICKIN'S KEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

TECHNICAL EDUCATION.

SCIENCE AND ART DEPARTMENT.

Royal College of Science for Ireland,

STEPHEN'S GREEN, DUBLIN.

SESSION—1871-72.

This College supplies, as far as practicable, a complete Course of Instruction in Science applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

There are Four Royal Scholarships, of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in College. There are also Nine Exhibitions attached to the College, of £50 each, with Free Education and Laboratory Instruction, tenable for three years. Three become vacant each year. These are awarded at the Annual May Examinations of the Science and Art Department.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory.

The Laboratory Fee is £12 for the full Course of nine months, or £2 per month.

SUBJECTS OF INSTRUCTION.

Applied Mathematics, Mechanism and Machinery, Descriptive Geometry, Geometrical, Mechanical, and Engineering Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology and Palaeontology, Mining, Surveying, Agriculture.

The Laboratory is open for Instruction in Practical Chemistry, Metallurgy, and Assaying, from ten to four o'clock every week-day during the Session, except Saturdays and Holidays.

The Session commences on MONDAY, OCTOBER 2.

Programmes may be obtained on application to the Secretary, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

THE CHEMICAL NEWS.

VOL. XXIV. No. 619.

ON THE EXISTENCE OF SULPHUR DICHLORIDE.*

By JOHN DALZIEL and T. E. THORPE.

WHEN dry chlorine in excess is passed through molten sulphur, a dark red fuming liquid slowly distils over. This on renewed distillation commences to boil at about 50° or 60°, and the thermometer slowly rises to 136° or 137°, at which point it remains stationary, and orange-yellow disulphide, Cl_2S_2 , passes over. The fraction boiling below 136° frequently amounts to three-fourths of the original quantity of liquid; on again submitting it to distillation, the same order of things is repeated, and but a comparatively small portion distils over 136°. At each distillation the liquid becomes lighter in colour, until at length, by long-continued boiling, it assumes the bright yellow tint of the disulphide, and boils constantly at 136° to 137°. This behaviour would seem to indicate the existence of some compound of chlorine and sulphur which slowly undergoes decomposition on distillation, ultimately forming the disulphide, and the observations of Dumas and Soubeiran, and of Marchand, Davy, and Rose, point to a body richer in chlorine than the disulphide, and their analyses lead to the formula SCl_2 . On the other hand, Carius denies the existence of sulphur dichloride in the dark red liquid obtained by heating sulphur in chlorine, and asserts that the compound analysed by Dumas and others was a mixture in atomic proportions of the disulphide with a tetrachloride of sulphur hitherto unisolated, $\text{Cl}_2\text{S}_2 + \text{SCl}_4 = 3\text{Cl}_2\text{S}$. According to Carius, the amount of chlorine contained in the liquid over and above that required by the formula S_2Cl_2 is altogether dependent on the temperature; but the fact of the protracted distillation required to break up the product into a liquid boiling constantly at 136° to 137° implies, however, that the excess of chlorine is held by some other force than that of mere solution; at the same time we are not altogether without facts more directly indicating the existence of the dichloride. Rose has obtained a compound of this body with the terchloride of arsenic, $2\text{AsCl}_3\text{Cl}_2\text{S}$, and according to Guthrie it yields with the olefines compounds of the general formula $\text{C}_n\text{H}_{2n}\text{Cl}_2\text{S}$. Hübner and Gueront† have lately made an observation, which also tends to support the idea of the existence of this body. A quantity of the pure chloride, S_2Cl_2 , was placed in a strong freezing mixture, and a current of dry chlorine passed through it for some time, the excess of this gas (that is, that existing merely in solution) being displaced by a stream of dry carbon-dioxide passed through for three or four hours. Whilst still in the freezing mixture a small quantity of the chloride was withdrawn and analysed, when numbers were obtained exactly agreeing with those required by the formula Cl_2S .

We have repeated this experiment with precisely the same result. A quantity of pure S_2Cl_2 was first prepared; it boiled constantly at 136° to 137°, and was analysed with following results:—

	Calculated.		Found.	
	I.	II.	I.	II.
S_2	64	47.42	..	..
Cl_2	71	52.58	52.48	52.67
	135	100.00		

About 20 grms. of this liquid were then saturated with chlorine in the manner described by Hübner and Gueront; after the excess of chlorine had been removed by carbon dioxide, it yielded the following numbers on analysis:—

	Calculated.		Found.		Dumas, H. & G.	
	I.	II.	I.	II.	I.	II.
S	32	31.07	..	..	31.9	30.5
Cl_2	71	68.93	69.25	69.06	68.1	69.3
	103	100.00			100.0	99.8

The existence of this body would therefore appear to be fully proven, for it is scarcely possible that such an agreement can be the result of an accidental coincidence.

From these experiments, therefore, we draw the same conclusions as those deduced by Hübner and Gueront, viz.—that there exist two compounds of chlorine and sulphur analogous to the oxides of hydrogen. First, a non-volatile chloride, having the formula SCl_2 , corresponding to H_2O , which on distillation splits up into chlorine; and the second, chloride, S_2Cl_2 , corresponding to peroxide of hydrogen, $2\text{Cl}_2\text{S} = \text{S}_2\text{Cl}_2 + \text{Cl}_2$.

It will be at once apparent that in one respect the analogy between these chlorides and the oxides of hydrogen is incomplete, in so far that the most stable oxide of hydrogen, is water, into which the dioxide is easily converted by heating, whereas the reverse of this happens with the corresponding sulphur chlorides, the most stable compound being the S_2Cl_2 , into which body and free chlorine the SCl_2 is resolved on heating.

ON THE COMPOSITION OF THE GASES EVOLVED FROM THE

BESSEMER CONVERTER DURING THE BLOW.

By GEORGE J. SNELUS,
Associate of the Royal School of Mines.

1. Design of the Investigation.

THE members of the Iron and Steel Institute will remember that Professor Roscoe, in his lecture on Spectrum Analysis, alluded to the difficulty of determining the cause of the greater part of the lines in the Bessemer spectrum, and pointed out, that while the majority of observers referred them to carbon in some form, there were others who believed them to be mainly due to manganese. Assuming the lines to be due to carbon, it is clear that an analysis of the gas producing the lines would be a step towards solving the difficulty, since it would show us which condition of carbon we must refer them to. This is important because we know that carbon in different gaseous combinations and at different temperatures produce, as Dr. Watts has pointed out, several distinct spectra.

Another question which suggests itself on examining the spectrum is, that supposing the characteristic lines are due to carbon, "How is it that the spectrum of carbon is not seen in the earlier stages of the blow, when an analysis of the metal proves incontestibly that carbon is being burnt in considerable quantities from the commencement?"

It appeared to me that analyses of the gas at different stages of the blow might help to a solution of these problems, for though it is generally assumed that during the process of conversion the carbon of the pig is burnt to carbonic oxide, this, as far as I am aware, has never been proved to be the case. It will be seen from the analyses, that this turns out to be only partially true, and that the composition of the gases evolved affords us an insight into the nature of the process going on that could not be supplied by analysis of the metal and slag at successive stages.

* Read before the British Association, Edinburgh Meeting, Section B.

† Zeitschrift für Chemie, xv., 1870, 455.

2. Method of Collecting the Gas.

The gas for analysis was collected by means of a long iron gas-pipe, on the end of which a swan-neck trumpet mouth-piece of fire-clay was fixed, which was inserted in the neck of the converter, after it had been turned up. This generally got clogged up with slag during the experiment, and therefore served only for one trial. It was allowed to dip into the vessel, so as to be certain that no air could be drawn into the tube by induction. To the other end of the pipe glass tubes were attached at particular periods of the blow when the gas was required, and sealed up with the blow-pipe before being removed. A constant stream of gas was allowed to rush through the tube the whole time, and as this was done for two minutes before the first sample of gas was collected, it may be safely assumed that the whole of the air was swept out, and that the gas analysed was a true sample of that produced by the direct action of the blast upon the metal and its constituents.

It was found that during the first part of the blow, the gas would not light at the end of the iron tube, but that from about the commencement of the boil to the end of the blow, it burnt with the pale blue flame characteristic of carbonic oxide.

Samples were taken every two minutes and subjected to analysis with the subjoined results.

3. Methods of Analysis Employed.

The gases were analysed in a modified form of the apparatus, described by Professor Frankland, for analysing the gases incident to water analysis, which was found extremely convenient. Samples 3 and 5 were analysed by different methods, the carbonic oxide in one case being estimated by absorption with a hydrochloric solution of subchloride of copper, and in the other by explosion with detonating gas and oxygen, and subsequent absorption by potash, after the method of Bunsen. It will be seen that the results agree closely.

4. Details of the Analyses of Gas, with Deductions therefrom.

Sample 1.—This was taken two minutes from the start of a blow which lasted 18 minutes. It contained:—

Carbonic acid	10.71
Oxygen	0.92
Carbonic oxide	none
Hydrogen (not estimated)	88.37
Nitrogen	100.00

This I considered to be an unlooked for result, because it is usually assumed that the carbon is burnt directly to carbonic oxide at all stages of the blow. Taking the nitrogen in this sample at 87 per cent, this corresponds to 23.05 vols. of oxygen. 10.71 vols. carbonic acid contain 5.35 vols. carbon vapour, which, referred to air as unity, represent 4.43 parts by weight of carbon. The carbonic acid contains its own volume of oxygen, which deducted from 23.05 leaves 12.34 vols. = 13.62 parts by weight of oxygen to combine with other elements than carbon. Now, ordinary English Bessemer iron contains little else for oxidation than carbon, silicon, and iron; the manganese being usually small in quantity, traces only of the sulphur disappearing, and the phosphorus remaining untouched. Of the three oxidisable elements, it is known from analysis of the slag that the iron is not burnt to any extent till towards the end of the blow, so that we have only to consider the carbon and silicon.

The 13.62 parts of oxygen may, therefore, be assumed to be combining with silicon alone, so that as 32 parts of oxygen unite with 28 silicon, or in the ratio of 8 to 7, we have 11.91 parts silicon being oxidised at this stage, along with 4.43 parts of carbon; thus showing that, though both elements are being oxidised, it is the silicon which

is disappearing most quickly. Now this is exactly what analysis of the metal proves, for a charge containing, on running into the converter—

3.57 per cent carbon

2.26 per cent silicon

was found by Mr. Barker in a few minutes to have lost—

0.53 per cent carbon and

1.305 per cent silicon.

As an example of the nature of the gas evolved at a point between the times when this first sample was taken and that obtained two minutes later, I give here analyses made by my friend, W. Thorp, F.C.S., of the Rivers' Commission Laboratory, of two consecutive tubes of gas which I collected four minutes from the commencement of a blow, which, from the converter being new, or the iron cold, lasted 29 minutes:—

	No. 1 tube contained.	No. 2 tube contained.
Carbonic acid	8.940	9.296
Oxygen	0.916	0.113
Carbonic oxide	0.078	0.044
Hydrogen	90.066	90.544
Nitrogen	100.000	100.000

Sample 2.—Taken four minutes from commencement; contained:—

Carbonic acid	8.57
Carbonic oxide	3.95
Hydrogen	0.88
Nitrogen	86.58
	100.00

It will be noticed that carbonic oxide is gradually increasing, while carbonic acid is decreasing in quantity.

Sample 3.—Taken six minutes from start; contained—

	By absorption.	By explosion.
Carbonic acid	7.89	8.20
Carbonic oxide	4.65	4.52
Oxygen	absent	absent
Hydrogen	—	2.00
Nitrogen	87.55	85.28
	100.00	100.00

Dissecting these results after the manner of those for No. 1, we find that 85.28 nitrogen correspond to 22.61 vols. oxygen. The carbon is combined with 10.46 vols., leaving 12.15 vols. (13.42 parts by weight) of oxygen, to combine with other elements. This will require 11.74 parts silicon, while the carbon going off as gas amounts to 5.27 parts. Carbon is, therefore, now being oxidised more rapidly in proportion to the silicon than was the case when No 1 sample was taken.

Sample 4.—This was taken ten minutes from the start, and as soon as possible after the boil had commenced. The complete spectrum was now visible and constant, and remained so to the end of the blow. The gas contained:—

Carbonic acid	3.58
Oxygen	none
Carbonic oxide	19.59
Hydrogen (not estimated)	2.00 (probably)
Nitrogen	74.83
	100.00

The great increase in the proportion of carbonic oxide, and corresponding decrease of carbonic acid, will here be noticed. This accounts for the increased luminosity of the flame at this period, as we have now a large volume of gas actually burning at the mouth of the converter. Assuming all the oxygen now being evolved in combination to be derived directly from the blast at present

passing through the iron, we have for the 74.83 vols. nitrogen 19.84 vols. oxygen entering the converter, but the carbonic acid contains 3.58 vols., and the carbonic oxide 9.79 vols., together 13.39 vols., in combination with carbon, leaving 6.47 vols. for other work. This would oxidise 6.25 parts silicon, and there are now 9.6 parts of carbon being burnt, so that the conditions are now reversed, carbon being oxidised at a more rapid rate than silicon. This is the point at which the carbon lines become well defined, and the analyses, we think, shows why this is so.

Sample 5.—Taken 12 minutes from start; gave—

	By absorption.	By explosion.
Carbonic acid ..	2.47 ..	2.30
Oxygen ..	absent ..	—
Hydrocarbons ..	absent ..	—
Carbonic oxide ..	29.58 ..	29.30
Hydrogen ..	— ..	2.16
Nitrogen ..	67.95 ..	66.24
	100.00	100.00

This sample of gas was specially tested for hydrocarbons, as being the most likely period of the blow to detect them if they were formed to any extent. But although the gas was left in contact with fuming sulphuric acid for 12 hours, no absorption took place. As the results by explosion agree in showing the absence of these gases, I think we may fairly conclude that none are formed.

Sample 6 was taken 14 minutes from start, and four minutes from end of blow. It gave—

Carbonic acid ..	1.34
Oxygen ..	absent
Carbonic oxide ..	31.11
Hydrogen (not estimated) ..	2.00 (probably)
Nitrogen ..	65.55
	100.00

The large percentage of carbonic oxide, and almost absence of carbonic acid, is remarkable, 65.55 parts nitrogen correspond to 17.37 oxygen, 16.89 vols. (18.66 parts by weight) are combined with 13.45 parts of carbon, leaving 0.53 parts of oxygen which would combine with 0.46 parts silicon; so that at this point it is practically carbon alone that is being oxidised, the last traces of silicon disappearing very gradually.

Looking through these analyses, we note the broad fact, that carbonic acid is formed in the first part of the blow with little or no carbonic oxide, while during the latter part, carbonic oxide is formed with only traces of carbonic acid. The question "Why is this?" suggests itself: why should the carbon take up twice as much oxygen at one time as another, under apparently the same conditions? My own impression is, that both this chemical reaction, and also the difference between this carbon spectrum and that from carbonic oxide, under ordinary circumstances, are functions of temperature. It is certain that at the commencement of the blow the temperature cannot be much above a yellow heat, while at the end of the blow it is undoubtedly a good white heat; now, it appears to me, that under the conditions in the converter, carbonic oxide is the most stable body at a high temperature, and carbonic acid at a lower one. This agrees with the experiment of our V.-P., I. Lowthian Bell, where he shows that the conditions of equilibrium for these gases in the presence of metallic iron are—

Low red heat ..	150 vols. carbonic acid	} for each 100 carbonic oxide.
Full red ..	47 " "	
Approaching whiteness }	11 " "	

It also agrees with the general observation, that if the iron is cold when it comes from the melting furnace, the period

of the boil is delayed, while if the iron has been kept in a reverberatory melting furnace for a considerable time at a high temperature, this period is reached more quickly. The action of the oxygen upon the silicon may have something to do with the degree of oxidation of the carbon, for I find that the time when the boil takes place depends closely upon the quantity of silicon contained in the iron. Thus, with pig containing about 2½ per cent silicon, the boil takes place about the middle of the blow, while with Swedish iron, which contains only about 1 per cent silicon, this point is, I believe, reached much sooner.

Alterations of temperature produce changes in spectra, and I think it will be found that this Bessemer spectrum, or at least that part of it which is due to carbon, is simply the spectrum at which it is burning at the mouth of the vessel.

5. Comparison of the Gas with Spectroscopic Appearances.

1st Stage—

	Spectrum observations show—	Analysis of the gas shows—
0 to 4'. Faint continuous spectrum. No actual flame.		Carbonic acid evolved but little or no carbonic oxide. Carbonic acid still
4 to 8'. Sodium, potassium, and lithium lines appear. Towards the close occasional flashes of carbon lines.		given off with but little carbonic oxide. The temperature, certainly rising and causing the volatilisation of alkaline metals.

2nd Stage—

8 to 10'. Dense flame. Bright carbon lines in red, blue, and green fields.		Carbonic oxide evolved in quantity and burning at a high temperature at the mouth of the converter.
10 to 14'. Bright green carbon lines more distinct.		Carbonic oxide much increased in quantity.
14 to end. Carbon lines bright till close, when they suddenly disappear.		Carbonic oxide still being evolved up to end of reaction.

6. Luminosity of the Flame.

It has been suggested by Mr. M. Williams (see *Nature*) that the great brightness of the flame might be due to hydrocarbons, but analysis shows that this supposition is untenable. I think it more likely that the reason why we get such a bright flame from carbonic oxide during the blow is, that it is burning at the mouth of the converter at a much higher temperature than we get when we ignite a jet of the cold gas; for it is evident that the carbonic oxide formed in the metal-bath must have even a higher temperature than the metal itself, and this is superadded to the temperature developed by carbonic oxide burning in air. This is in accordance with the explanation given by H. Ste.-Claire Deville and Kirchhoff of the increase of luminosity of flames when burnt under great pressure, viz., that the temperature of the flame is thereby increased.

7. Comparison of Converter Gas with Blast-furnace Gas, and with Gas from Siemens's Producer.

It may be interesting to compare the composition of the gas during the latter part of the blow with other available gases met with in iron works. I have selected as blast-furnace gases a sample of gas from a Cleveland furnace, by I. L. Bell, Esq., and one from a Bessemer furnace, by Wm. Crossley, Esq., and have added two samples of gas from Siemens's producers at Dowlais, which I have recently had occasion to analyse.

	Siemens's producer gas.		Bessemer con- verter. Mean composition of gas during last half of the blow.	Cleveland B. Fce. Gas.	Askam Fce. on Bessemer pig.
	I.	II.			
Carbonic acid	4'3	5'2	1'34	17'30	8'36
Carbonic oxide	25'6	24'4	31'11	25'20	34'97
Hydrocarbons	2'8	trace	—	—	—
Marsh gas	1'6	2'4	—	—	—
Hydrogen	—	8'6	2'00	0'10	2'16
Nitrogen, &c.,	65'7	59'4	65'55	57'40	54'51
	100'0	100'0	100'00	100'00	100'00

8. Value of the Gas as Fuel.

It will be seen from these analyses that the gas from the Bessemer converter during the last half of the blow is really of as much value as any gas made purposely, or incidentally, at an iron works. This is a most important fact, and if we consider the amount of fuel thus going to waste the question naturally suggests itself whether it cannot be made available.

If we assume that during the latter half of the blow two-thirds of the total carbon in the pig is burnt, and take the melted iron to contain $3\frac{1}{2}$ per cent carbon, we find that a Bessemer works, using only 1000 tons of such pig per week, is wasting a quantity of fuel equal to $23\frac{1}{2}$ tons pure carbon, or say 25 tons coke.

9. How the Gas could be made available.

Now, I would suggest that it is possible, by simple mechanism, to collect this gas and pass it under boilers, when it would save its equivalent of coal. The large body of flame is not wanted for any purpose. True, the workman now depends upon its indications to afford him the means of judging when the blow is completed, but the spectroscope would do this with greater accuracy with a fraction of the gas which now roars from the converter.

The nature of the gases evolved during the blow will, of course, vary with the quality of the iron used, but as

it is not possible to use iron with much less than 3 per cent carbon, the quantity of carbonic oxide evolved cannot be much less than that found in the foregoing analyses, and I believe that whatever may be the nature of the iron, the general results will be the same. It would be interesting to have a similar series of analyses of gases from highly manganiferous pig for comparison, and I trust that other workers in this interesting metallurgical department will supply the deficiencies which my own analyses leave.

Dowlais Laboratory,
August, 1871.

PREPARATION OF HYDROSULPHURIC ACID.

By JOHN GALLETTY.

In making some experiments on the action of sulphur on paraffin, I have found that a mixture of these substances, either in equal parts or with a larger proportion of sulphur, when heated in a flask not greatly above the melting-point of the sulphur, begins to evolve hydrosulphuric acid, and continues to give off this gas steadily, while kept moderately heated, for a considerable time.

I have used this process repeatedly, and consider it the most convenient for laboratory use. With a round flask holding about a pound of the materials fitted with a tube bent at right angles about $\frac{1}{4}$ -inch bore and 12 to 18 inches long, containing a little loose cotton wool, and having a smaller tube fitted to the end of this for dipping into the liquid through which it is desired to pass the gas, a convenient stream can be obtained lasting several days. The production of the gas can be stopped and renewed at pleasure by withdrawing or applying the heat. An Argand lamp should be employed, or if a Bunsen is used, the top

piece should be on the tube for spreading the flame, so as to avoid heating the flask on one spot. Heavy paraffin oil used for lubricating machinery can be substituted for the solid paraffin, and good results are also obtained with commercial stearic acid, but with the latter the tube conveying the gas soon becomes covered with drops of a milky liquid, which is probably water and finely divided sulphur. With paraffin the tubes remain clear and bright, except for a little sulphur sublimate close to the neck of the flask.

I observe that Reinsch recommends a laboratory process for obtaining pure sulphydric acid by heating in a glass flask equal parts of sulphur and suet. The recommendation does not seem to have been generally followed, but the advantages resulting from the substitution of paraffin for suet may lead to the more usual adoption of this process.

Addiewell Chemical Works.

ON A NATIVE SULPHIDE OF ANTIMONY FROM NEW ZEALAND.*

By M. M. PATTISON MUIR, F.C.S.

Student in the Laboratory of the Andersonian University,
Glasgow.

In the gold mines at the Thames, New Zealand, there are found tolerably large quantities of grey antimony ore, or stibnite, associated with the quartz and other rocks of the older series, from which gold is extracted.

The analysis of a sample of this stibnite, which I obtained about a year ago, I have now the honour to lay before the Association.

The sample had the appearance of a large mass of steel grey crystals, radiating chiefly from a central point; some of the crystals being fully an inch in length, and generally very perfectly formed. The crystals were prisms belonging to the trimetric system, soft, and easily cut with the knife in the direction parallel to the principal axis, showing, when cut, a brilliant metallic lustre.

Adhering to the crystals was a small amount of gangue, composed seemingly of siliceous matter.

For the purpose of analysis a large crystal was broken off perfectly free from any foreign matter. The specific gravity of the crystals = 4.625. The following are the results of the analysis:—

Antimony	71.09
Iron	0.24
Arsenic	traces
Sulphur	28.47
	99.80

ON THE CAUSES OF THE PHENOMENA OBSERVED WHEN THE BESSEMER FLAME IS VIEWED THROUGH COLOURED GLASSES.

By J. SPEAR PARKER,

Chemist to the Cyclops Steel and Iron Works, Sheffield.

In a former communication (CHEMICAL NEWS, vol. xxiii, p. 25), I described the appearances seen when the Bessemer flame was observed through a combination of a blue and a deep amber or orange glass. I should not be surprised if others have failed in obtaining such well marked alterations in the colour of the flame as I there

mentioned, for a very small variation in the depth of colour of the glass used is sufficient to mar the effect. Out of two dozen glasses obtained ostensibly of the same colour, I was only able to select four or five which gave the required result. If either the blue or the orange be too deep, the flame has a reddish appearance throughout, only showing different shades of red and crimson; if, on the other hand, the colour be not deep enough, the flame at the beginning and end of the process is more of a light orange than crimson, and during the period in which the carbon spectrum is exhibited appears of a much greener colour. The combination may be a little varied, however, without any great detriment if a little deeper blue be compounded with a somewhat lighter orange or vice versa.

I anticipated that the changes in colour of the flame when viewed through these glasses were owing to the nature of the spectrum given by the flame, and an examination of the absorption exercised by these glasses has confirmed my conjecture.

As before, the spectroscopic I used was a direct vision instrument with five prisms; on placing the blue glass before the slit and viewing direct sunlight, a spectrum was obtained containing well-defined dark bands. The least refrangible portion of the spectrum from A to a little beyond B was transmitted apparently without any diminution of brightness, then a very intense black band appears extending beyond C; another dark band occurs with the line D in the centre, and between these two partial absorption takes place, only a faint reddish light being visible; on the termination of the band beyond D, a clear bright space occurs in the yellowish green, and again a broad absorption-band, not so dark as those previously mentioned, extends beyond the lines E and b, the blue and more refrangible portion being freely transmitted. If a double thickness of glass be interposed, the space from near B to beyond D appears as one broad dark band, while the light admitted in the yellowish green has been more rapidly absorbed than that in the red.

With one thickness of orange glass, the red, orange, and yellow are freely transmitted, but the more refrangible rays are absorbed with gradually increasing intensity till light is scarcely visible beyond F. With two thicknesses, though the red is little affected, even the yellow seems scarcely so bright by comparison, and all is darkness beyond E.

With the combination of one blue and one amber used for observing the Bessemer flame, the bright red band is seen as through blue glass, then the first dark band, again faint reddish light, the second dark band, the bright yellowish green space, again a broad absorption-band, while the blue and violet are dimly visible. Without further experiment this explains why increased depth of either colour should render the flame as seen through the combination redder, for both glasses absorb the green and blue more rapidly than the red rays; hence, if these were first balanced, increased depth would cause the red to predominate. An examination of the Bessemer flame by means of the spectroscopic, with a blue glass interposed, shows the cause of the curious alterations in the colour, and why they agree with the indications of that instrument. When the carbon spectrum was fully developed, I found that the most prominent and brilliant group of lines occurring in that spectrum—the first in the green—fell in the centre of the second bright space. The potassium line is visible in the extreme red, but the lithium line, on the contrary, falls in the first dark band and is invisible; the first red group in the carbon spectrum is almost obliterated, and there is but a faint indication of the sodium line, then appears the bright space with the triple group in the centre, the remaining green lines, &c., being again obscured.

Hence when the flame is first observed the red light predominates, the flame appears crimson. As soon as the carbon lines flash through the spectrum, yellow flashes are seen through the glasses, and shortly the flame pre-

* Read before the British Association, Edinburgh Meeting, Section B.

sents the appearance of a light gamboge-yellow, a rose-coloured cone in the centre, and crimson edges. The production of this yellow, I think, is an additional illustration of the compound nature of that colour, for the red which previously predominated has added to it additional green light (in consequence of the appearance of the group of bright lines) and the result is yellow. However, it might be explained on the old principle, that the green being of a yellowish tint, the red and true green neutralise, the excess of yellow predominating. The central rose-coloured cone corresponds to the hollow of a Bunsen's flame, where no combustion can occur, and consequently the characteristic spectrum is not produced. With regard to the crimson edges, it is possible that here the carbon lines are not developed, complete combustion having occurred. In the "spiegel flame," as I before remarked, the green groups are brighter and more prominent than in the ordinary spectrum, and this gives a greenish yellow hue when seen through the glasses. I think the slightly different appearances observed by Mr. Rowan, and Professor Silliman, are easily explained. Mr. Rowan used two blue glasses, which though doubtless of a lighter tint than the one I employ, together caused the red to predominate throughout, as previously explained. Professor Silliman, while using one blue, used two *light yellow* glasses; hence the absorption of the more refrangible blue and violet might not be sufficiently complete, and the blending of those colours would cause the ashy blue, &c., which he observed.

As these changes are shown to be owing to the disappearance of the carbon lines, the glasses may be used with greater confidence in the accuracy of their indications; and for use in the workshop are much better adapted than a delicate instrument like the spectroscope.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

PHYSICAL AND MATHEMATICAL SECTION.

March 28th, 1871.

E. W. BINNEY, F.R.S., F.G.S., President of the Section, in the Chair.

MR. BROTHERS, F.R.A.S., after some preliminary remarks as to the chief objects of the English Eclipse Expedition to Sicily, in December last, exhibited on the screen a series of photographs illustrating, in the first instance, the means adopted for obtaining photographs of the eclipse. A series of pictures was then shown illustrating the corona as photographed during the eclipses in 1860, 1868, and 1869, and the whole of the pictures taken during the totality in 1870 at Syracuse. These were shown in comparison with the pictures taken in Spain by the American observers, and also with sketches taken by members of the English expedition in Spain. These illustrations showed in a remarkable manner the advantages of photography in depicting phenomena such as are seen during eclipses of the sun—the strict identity of the positions of the rifts or dark spaces in the corona being shown most perfectly. The identity of those rifts was also shown by comparison with a drawing made by Professor Watson at Carlentini, in Sicily.

During the evening Dr. Roscoe, F.R.S., explained the importance of spectrum analysis in investigating the solar phenomena, and described the preparations he had made for viewing the eclipse from his station on Mount Etna, about 5000 feet above the sea-level.

The photographs and other illustrations were exhibited by means of Mr. T. Harrison's powerful electric apparatus.

Annual Meeting, April 25th, 1871.

E. W. BINNEY, F.R.S., F.G.S., President of the Section, in the Chair.

The following gentlemen were elected Officers of the Section for the ensuing year:—

President—Joseph Baxendell, F.R.A.S.

Vice-Presidents—E. W. Binney, F.R.S., F.G.S., Alfred Brothers, F.R.A.S.

Secretary—G. V. Vernon, F.R.A.S., F.M.S.

Treasurer—Thomas Carrick.

"Performance of the Electro-Magnetic Engine." By the Rev. H. HIGHTON, M.A.

(1). I am sure that Dr. Joule is a sufficient lover of truth not to feel offended if I submit his last explanations on this subject to the test of facts and experiments.

Not having myself the means of trying experiments with sufficient accuracy to venture to publish results, I will make use only of M. Favre's and Dr. Joule's own experiments.

(2). The whole basis of Dr. Joule's new reasoning is, that when a magnetic engine works rapidly less heat is evolved and more absorbed in it. Taking his own figures as a basis, I find he calculates that when the current is reduced to one-half what it was when the engine was at rest, the heat evolved *per hour* would be one quarter, and *per equivalent of zinc* consumed one-half. Now let us take the measurement by M. Favre's calorimeter (*Comptes Rendus*, vol. xlv.). When the engine was at rest, the calorimeter in which it was placed showed, per equivalent of zinc consumed, 2219 heat-units. When it worked slowly, raising a weight, it evolved 2947 units, and when it worked rapidly, raising no weight, it showed 4769 units. In that case, therefore, the effect was exactly the reverse of what Dr. Joule supposes.

(3). I have taken Dr. Joule's own experiments described in the *Philosophical Magazine*, vol. xxviii., and have calculated, on the data he gives, what weight ought to have been raised in each experiment. I subjoin a table of what should have been raised and what actually was raised:—

Expt.	Foot-pounds calculated.	Actual.
I.	19,377	21,100
II.	18,628	17,820
III.	11,533	8,800
IV.	11,232	9,000
V.	17,416	10,031
VI.	18,033	12,673

In order that any mistake I may have made may be detected, I subjoin the calculations themselves in an appendix. The numbers are calculated on the supposition that the resistance of the battery could be neglected. If Dr. Joule in those experiments acted on the erroneous principle, into which he was misled by Jacobi, that the resistance of the wire should be equal to that of the battery, each of the above calculated numbers should be reduced by one-half, which, in every case, would make the work actually done considerably more than the calculation, in some cases more than double.

(4). Let me next observe that if, instead of a wire 389 feet long, and 1-16th of an inch in diameter, Dr. Joule had taken one which was half the length and half the section, all his figures would apply equally well; or, again, a wire of German silver a quarter the length, and with four times the resistance; or, to take an extreme case, a wetted cord enclosed in an insulating tube 1-rootth part the length, and with 100 times the resistance.

(5). Dr. Joule when he demonstrates that there is no variation in economy, whatever the arrangement of the conducting metal, or whatever the size of the battery, demonstrates too much; for it would follow from this,

that no diminution in the size of the battery would affect the result injuriously. Why, then, should he prescribe a battery of such a size that the resistance may be neglected? Take, again, his own figures in the 4th vol. of "Sturgeon's Annals." By reducing his battery from 40 pairs to 10, he increased his economic duty from 65·00 to 97·00 or 50 per cent.

(6). But in reality Dr. Joule's views in 1840 were more correct than they are now; for he was then not so far committed to the theory of the mechanical equivalence of heat. In 1840 he allowed that an economy could be effected by increasing the quantity of wire. Let us see whether he was right then, or whether he is so now. In his experiments in 1845 he used twice as much wire in his first two experiments as in his four last. What was the consequence? In his first two experiments the average of foot-pounds per hour was 19,460 and duty per grain of zinc 98·35. In the four last experiments the average per hour 10,125, and duty per grain of zinc 51·8, thus clearly showing, that doubling the quantity of wire nearly doubled both the actual work done and the economical duty.

(7). Again, a comparison of his two first experiments would tend to prove that reducing the intensity below one-half reduces not only the work done per hour, but the duty also, instead of increasing it. For the full current being 2232, a reduction to 920 produced 21,100 foot-pounds of work per hour, and a duty of 102·9; whereas a reduction to 850 (by increasing the turns from 140 to 180 per minute) produced only 17,820 foot-pounds of work per hour, and a duty of only 93·8, or nearly 10 per cent less.

(8). Dr. Joule's accurate and most valuable experiments are still the great storehouse of facts on this subject. What I contend is, that they disprove, not prove, his own theory.

Dr. JOULE said in noticing Mr. Highton's remarks,—I would refer him to my paper on the calorific effects of magneto-electricity and the mechanical value of heat, published in the *Philosophical Magazine* for 1843, vol. xxiii. He will there find it stated, pp. 274, 351, as the result of my experiments, that the heat evolved by the wire of my revolving electro-magnet varied with the square of the current passing through it, and was not affected by the resistance presented by magneto-electric induction in consequence of the working of the electro-magnetic engine. This fact is the basis of my reasoning in that paper, and the neglect of it has involved Mr. Highton in error, as may be seen in his reply to Mr. Apjohn's most lucid exposition of the true theory in the *CHEMICAL NEWS*, vol. xxiii., p. 105.

The correctness of Jacobi's formula for the proper arrangement of the wires of a battery to produce the maximum magnetic effect is not necessarily connected with the subject of economy of work. Nevertheless I may refer Mr. Highton to my experiments on this subject in "Sturgeon's Annals" for 1839, by which I showed that the attraction of electro-magnets for one another is proportional to the square of the current between very wide limits.

Mr. Highton seems to forget, when commenting upon the large amount of duty obtained in the first two experiments of my paper with Scoresby, that in them the theoretical duty was also greater than in the others, owing to the current being worked down to a lower intensity. Another reason, explained in the paper was, that in those two experiments, recently mixed, and therefore hot solutions were used in the battery, the potential of which was thereby increased.

Mr. Highton is in error if he supposes that my paper in the *Proceedings* for March 21st contains a new theory, or that I have abandoned any of my original views. My object in that paper was simply to place the true theory in a form in which it might be easily understood by those who have not worked on the subject.

NOTICES OF BOOKS.

Alkali Act, 1863. Seventh Annual Report by the Inspector of his Proceedings during the year 1870. Presented to both Houses of Parliament by command of Her Majesty, 1871. Eyre and Spottiswoode.

The end for which the Alkali Act was passed, may be considered as attained; but there has arisen from the indefatigable labours of Dr. Angus Smith, a new branch of chemical science—chemical climatology. The importance of this new science it would be difficult to exaggerate—the likelihood that in a few years there will be some standard to which may be referred the paradoxical conclusions drawn from the statistics of the death-rate in towns as an indication of their healthiness, must claim for it almost general attention. The results of Dr. Smith's endeavours to establish such a science form the principal portion of the report for this year. He says:—

"The results do not in principle differ from those obtained last year, but the figures are more numerous, and it seemed advisable to calculate again the averages, often adding the new experiments. This has been done for the rain.

It has appeared to me necessary to examine the atmosphere in order to see what amount of muriatic acid it contained in places where that is manufactured. From that I was led to examine it also in other places, in order to make a full series of comparisons, and next I was naturally conducted to a comparison of the amount of muriatic acid and chlorides in relation to other substances. This part of the work may now be said to be accomplished, and the results, I hope, will be of use in all sanitary inquiries in future whenever the chemical method is adopted. That it will be adopted more frequently now is my belief. It is safer to examine the condition of the air by a few chemical experiments than by waiting to see how many deaths take place in a thousand of the population."

The report first considers the method of introducing the air into sample bottles; both the air-pump and a loose bellows-pump were employed. The results proved that the cumbrous air-pump might well be dispensed with for the bellows-pump, thus admitting the collection of samples with greater facility. Then follows an examination of the rain for different localities, the Inspector placing more reliance on air-washings than on the examination of continued rain, because when very wet the rain gives an exaggerated idea of the purity of the atmosphere; and when the season has been very dry, there obtains, on the other hand, an exaggerated idea of the impurities. The amount of chlorides in the rain depends mainly on two causes—the distance from the sea, and the distance from manufactures. Valencia has been taken as 100, as affording a good specimen of sea atmosphere. Sulphuric acid or sulphates measures the manufacturing activity and also the decomposition, the amount increasing inland on account of vegetable and animal matter. Ammonia, the result of decomposition, is a measure of the sewage in the air; but by itself it is not impure. On the contrary, the amount of albumenoid ammonia is a measure of the non-purified sewage in the air, and includes the most dangerous substances, germs of living things, vegetable or animal.

The following are some of the comparative results:—

				Parts per million.
Ireland, Valencia	1'00	..	..	0'034
Scotland, inland	1'26	..	..	0'043
" sea-coast	3'11	..	..	0'1055
England, inland	3'15	..	..	0'108
German specimens	3'59	..	..	0'122
Liverpool	4'67	..	..	0'159
Runcorn	5'59	..	..	0'190
London	6'03	..	..	0'205
Manchester, 1869	6'21	..	..	0'211
Manchester, 1870	8'32	..	..	0'283

	Parts per million.
Scotland, towns (not Glasgow)	6.23 0.212
England, (6 manufacturing towns)	6.26 0.213
Glasgow	8.82 0.300

But these are not a tithe of the many observations. There is one very notable fact, that in all the tables the result always shows badly for Glasgow.

In the case of the practical application of the Alkali Act, Dr. Smith advises, where damages are complained of relatively to two or more works in the locality, that a system of valuation should be established, so that the well-regulated works should not suffer equally with the careless manufacturer. He says:—

"Such a system if acted on by authority might be united with the first extension of the Alkali Act. It would give a right of inspection of works from which acids escape, at least when complaints were made. Coal smoke may some day be included, especially when people for economy burn a very inferior coal. To confine the extension to acids would avoid any great innovation. Acids are easily estimated, and it would be enough to give the acidity without stating the separate amount of each acid. We cannot very easily distinguish the different effects, and it is of little consequence to a man whether his land is poisoned by muriatic acid or sulphuric. At present this kind of distinction is the only consolation I can give to those who complain of injuries done by gases other than muriatic acid, and these complaints are the more numerous class."

CORRESPONDENCE.

ON THE CHARRING-POINT OF TEXTILE FABRICS.

To the Editor of the Chemical News.

SIR,—In connection with the concluding portion of Dr. Crace Calvert's experiments "On the Action of Heat on Protoplasmic Life and on Cotton Fabrics," and reported in the *CHEMICAL NEWS* of last week, permit me to mention that two and a half years ago I made a number of experiments in this direction, when altering the disinfecting chamber belonging to this borough, where previously the temperature rarely exceeded 212° to 220° F.

The object, of course, was to determine a safe point up to which the heat of the chamber could be raised, without damaging the clothing and bedding through scorching, placed there for supposed disinfection.

The substances taken were thin deal shavings, coarse bleached flannel, tissue-paper, piece of mohair dress, piece of print dress, piece of print muslin, piece of curtain muslin, together with some cotton-wool.

All the specimens were suspended freely, so that the heated air came fully in contact with every part of them; the thermometer was also similarly suspended. After half an hour's exposure at 200° F., and afterwards a like time at 250° F., the whole were found to be intact and unchanged. At 290° F. the fabrics, or some of them, gave off a vapour having the odour of scorching; but at 300° F. they were without visible detriment or change of colour. On continuing the heat for half an hour at 330° F., the shavings were found of a faint brown colour, barely perceptible; the other samples were of a slightly higher colour. The cotton-wool possessed a scorched smell, but such was not discernible in any of the others.

The temperature was now raised to 350° F. and continued as in each of the other tests for half an hour. The colour of each experimental piece was a little heightened, the cotton-wool and the flannel most so, whilst least of any the tissue-paper and print muslin.

I did not consider, judging from previous and more recent experiments, that the colouration was permanent, but would wash out, nor that the fabrics were at all damaged.

Half an hour's exposure at 365° to 370° F. gave a permanent scorching to all the specimens, the shavings, however, least so. At this temperature all the pieces were considered as damaged, although not materially.

I have always taken the view mentioned by Dr. Calvert, that the ordinarily employed temperatures of disinfecting stoves are inoperative upon germ life, and the virus of contagia. It is only right, however, to state that in this town the Public Chamber has the furnace within it, and as coke is the material employed, the whole place with the articles under treatment is impregnated strongly with sulphurous acid that very likely has a destructive action upon germs. Nevertheless, I am strongly of opinion that much more satisfactory results would be attained by thoroughly impregnating infected materials with the vapour of phenol at a moderate temperature, and in the presence of steam.

The results here arrived at as to the destructive action of heat upon such things as are likely to require disinfection, differ from those recorded by Dr. Calvert; but it must be noted that the conditions of experiments vary, the present ones are more in accordance with actual practice.—I am, &c.,

RICHARD WEAVER, C.E.

The Sanitary Laboratory,
Leicester, Sept. 25, 1871.

THE LECLANCHE BATTERY.

To the Editor of the Chemical News.

SIR,—I find that what I said about the Leclanché battery at the Post Office has led to a false impression, which I am asked to correct. I learn on the best authority that it is used only on circuits of considerable resistance, and not much work, for which it is found very suitable. I had good authority for what I said, but it no doubt referred to some isolated trials on short circuit, and with hard work. It is obvious that it would not be ordinarily used for such purposes.—I am, &c.,

H. HIGHTON.

Putney, Oct. 2, 1871.

VALENCY OR ATOMICITY.

To the Editor of the Chemical News.

SIR,—A reply to "W. H. O's." letter in the *CHEMICAL NEWS*, vol. xxiv., p. 156, will be found in two principles of the modern theory of atomicity.

Let me illustrate the first by diatomic oxygen. The molecule of oxygen gas contains two atoms, and the theory regards these as united by each of the atomicities of 1 atom being engaged or satisfied by an atomicity of the other, or, in other words, by an "exchange of two atomicities." But we may conceive two oxygen atoms united by exchanging only one atomicity, leaving vacant another in each atom, and so forming the diatomic radical (O_2). The molecular constitution of ozone, (O_3), proves the existence of such a radical. Hence—

(1). Two atoms of a polyatomic element may, by an exchange of atomicities, give rise to a radical of an atomicity corresponding to the number of points of affinity left vacant.

The second principle might almost be called an extension of the first. It is—

(2). In a single atom of a polyatomic element, a pair, or several pairs, of the atomicities may satisfy each other.

This leads to a distinction between atomicity and valency. The former is invariable, being determined by

the greatest number of monatomic atoms (or radicals) which an atom ever fixes. But the valency of the same atom may vary from one molecule to another, for it denotes only the number of atomicities which the atom actually satisfies in a given molecule. Obviously this will either equal the atomicity, or be less by some *even* number.

Fe is now regarded as hexatomic, from its analogy with Cr, and from its maximum valency, exhibited by potassium ferrate, $\text{Fe}\left\{ \text{O}^{\text{VI}}_2(\text{KO})_2 \right\}$. By (2), it may also be quadrivalent, as in FeS_2 ; or bivalent, as in $\text{Fe}^{\text{IV}}\text{O}$. By (1), two quadrivalent atoms can exchange an atomity and produce the sextivalent radical, $(\text{Fe}^{\text{IV}}_2)^{\text{VI}}$.

The pentatomicity of N is proved by its maximum valency in $\text{N}(\text{H}_4\text{Cl})^{\text{V}}$. By (2), it may be trivalent as in $\text{N}^{\text{III}}\text{H}_3$, or monovalent as in $\text{O}(\text{N}^{\text{I}}_2)^{\text{I}}$. Nitric oxide appears anomalous, but just as N_2O_4 splits up into 2NO_2 at a temperature below 100° , so NO may be the result of *dissociation* by even an extremely low temperature, and the true formula for nitric oxide $(\text{N}^{\text{IV}}_2)^{\text{IV}}\text{O}_2$.—I am, &c.,

R. ROUTLEDGE, B.Sc.

Bowdon, Cheshire,
Sept. 30, 1871.

ESTIMATION OF PHOSPHORIC ACID.

To the Editor of the Chemical News.

SIR,—In answer to Mr. B. J. Grosjean's questions (CHEMICAL NEWS, vol. xxiv., p. 33) relative to my paper on the above subject, I would say that by "pure aluminic sulphate" I meant, not the normal salt, but one that contained only aluminic, sulphuric, and hydric oxides. Had I used the normal salt I should not have published results obtained by so old and well-known a process as that of the estimation of aluminic oxide by ignition. The same is true of the ammonio-sodic phosphate.

I should be very much pleased if Mr. Grosjean would give us the results which he has obtained, both by the aluminic sulphate and the mercurous nitrate processes.—I am, &c.,

CHARLES E. MUNROE.

Cambridge, Mass., U.S.A.,
Sept. 1, 1871.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 4, 1871.

This number contains the following original papers and memoirs bearing upon chemistry and allied sciences:—

Relation Existing in the Sun between the Protuberances and other Remarkable Parts.—Rev. A. Secchi, S.J.—A lengthy and very interesting memoir elucidated by engravings.

Some Observations on the Simultaneous Distillation of Water and of certain Alcohols Soluble therein.—J. Pierre and E. Fuchot.—The conclusions which may be drawn from the facts communicated in this exhaustive essay are:—When a mixture of water

and amyl alcohol, or of water and butylic alcohol, is submitted to distillation, the temperature of the boiling liquid remains the same until there remains in the retort only one of the two liquids. This temperature of ebullition is always lower than that of the boiling-point of the most volatile of the two liquids—in the instance here mentioned below 100° . For each of these mixtures there exists a constant *rapport* between the proportions of water and alcohol which pass over by distillation, but this *rapport* varies with the varying alcohols, being 2 to 3 in the case of amyl, and 1 to 5 in the case of butylic alcohol and water mixed. When a mixture of butylic and amyl alcohol is made along with water, the temperature of the ebullition is not constant, but varies according to the varying proportions of the alcohols used for the mixture; but the boiling temperature remains always lower than the boiling-point of the most volatile liquid present.

On Petroleum.—H. Byasson.—This memoir treats on petroleum as regards its composition, its industrial applications, its origin, and the best means of ascertaining its inflammability; this latter particular is ascertained by the measurement of the pressure of the vapours of the petroleum exerted upon a column of water—a kind of manometer tube.

Spectra Exhibited by Carbon, Boron, Silicon, Titanium, and Zirconium.—L. Troost and P. Hautefeuille.—The contents of this highly valuable paper are not suited for useful abstraction; an observation also relating to the following paper:—

Spectra of Sulphur, Selenium, and Tellurium.—A. Ditte.

Preparation and Properties of a Sulphuret of Selenium.—A. Ditte.—After referring to the researches of Berzelius on this subject, the author states that he has prepared a crystalline compound of the two elements alluded to, by the action at a low temperature (between 0° and 5°) of sulphuretted hydrogen on a concentrated solution of selenious acid, and by purifying the precipitate thus formed by the aid of benzine and sulphide of carbon. The resulting compound is a crystalline, orange-yellow, transparent substance, consisting, in 100 parts, of:—Sulphur, 28.68; selenium, 71.40. This body is produced by the following reaction:— $\text{SeO}_2 + 2\text{H}_2\text{S} = 2\text{HO} + \text{SeS} + \text{S}$. The free sulphur is soluble in benzine or sulphide of carbon; sp. gr. of the compound, at $0^\circ = 3.065$.

Formation of Secondary Monamines by the Action of the Bases of the Formula $\text{C}_n\text{H}_{2n-7}\text{N}$ upon the Chlorhydrate of Naphthylamine.—C. Girard and G. Vogt.—The contents of this paper (the first instalment of a memoir on this subject) are, notwithstanding their intrinsic value, not suited for abstraction, on account of the large number of lengthy and complex formulæ required for the proper elucidation of the subject.

Jahrbuch der Kaiserlich-Königlichen (Austro-Hungarian) Geologischen Reichsanstalt, No. 2, 1871.

In addition to a number of papers treating on the geology and mineralogy of the Austro-Hungarian Empire, this number contains the following papers relating to chemistry and allied sciences:—

Phosphorite Deposits Situated on the Banks on the Dniester, in Russian and Austrian Podolia, and in the Bukowina.—F. Schwackhofer.—This lengthy essay, illustrated by several tabulated forms and engravings, treats on the phosphorite in a mineralogical, genetical, and chemical point of view. It appears that, on the whole, the deposits of this mineral are very rich in phosphoric acid, and in many respects the composition of the nodules of this phosphorite approaches that of pure apatite. Among the minerals, petrified wood is met with, which has a hardness = 4; sp. gr., at $17^\circ = 2.937$. The percentage composition of this mineralised wood (which, however, has a distinctly organised structure, and has been thereby ascertained to belong to the *Pinus* species) is:—Triassic phosphate of lime, 67.46; free phosphoric acid, 2.26 (the wood exhibits an acid reaction when brought into contact with moistened litmus-paper); fluoride of calcium, 9.33; carbonate of lime, 13.56; carbonate of magnesia, 0.96; sulphate of lime, 3.26; oxide of iron, 0.26; alumina, 0.05; silica, 0.04; organic matter, 2.99; water, 0.44.

Simple Instrument for Detecting, as well as Measuring, the Intensity of Earthquakes.—Dr. E. Stahlberger.—The description of an ingeniously arranged contrivance; illustrated by engravings.

Microscopical Investigation of the Pechstein of Corbitz.—Dr. B. Behrens.—The mineral alluded to is an unsilicified which, from its more pitch-like glass-like appearance, is termed pitch-stone. The contents of this paper treat on the microscopical structure of this mineral, which structure is illustrated by several engravings.

Account of the Analyses and Investigations Made in the Laboratory of the Geological Institute.—K. Ritter von Hauer.—This exhaustive paper contains the results of a very large number of analyses and investigation of various minerals, including coals, coke, brown coal, peat, pyrites, limestones, iron, and other mineral ores; these analyses are chiefly of local interest only.

The American Journal of Science and Arts, September, 1871.

This number contains the following original papers relating to chemistry and allied sciences:—

Nature and Duration of the Discharge of a Leyden Jar Connected with an Induction Coil.—O. N. Rood.—Second part of an essay on this subject, illustrated with woodcuts and diagrams.

Memoranda Concerning the Introduction of the Manufacture of Spelter into the United States.—J. Wharton.—An important contribution to the metallurgical industry of the great Trans-Atlantic Republic.

Destructive Distillation of Light Petroleum Naphthas at Comparatively Low Temperatures.—S. D. Hayes.—Reserved for reproduction; an observation also applying to the following paper:—

Observations on the Colour of Fluorescent Solutions.—Dr. H. Morton.

Mineralogical and Chemical Composition of the Meteoric Stone that Fell near Searsport, Maine, May 21, 1871.—J. L. Smith.—The sp. gr. of the specimen examined = 3.701. Nickeliferous iron and stony matter separated by mechanical analysis gave, for 100 parts:—Stony matter (including a little sulphur of iron), 85.38; nickeliferous iron, 14.62. The iron afforded:—Iron, 90.02 per cent; nickel, 9.05; cobalt, 0.43; phosphorus and copper, not estimated. The portion soluble in nitro-hydrochloric acids (soluble, 52.3 per cent; insoluble, 47.7) gave, in 100 parts:—Silica, 40.61; protoxide of iron, 19.21; magnesia, 36.24; sulphur of iron (accidental constituent, only present as mechanical mixture), 3.06. Composition of insoluble part:—Silica, 56.25 per cent; protoxide of iron, 13.02; alumina, 2.01; magnesia, 24.14; alkalis, NaO.KO, with trace of LiO, 2.10. Composition of stone:—Nickeliferous iron, 14.63 per cent; magnetic pyrites, 3.06; olivine, 43.04; bronzite, a hornblende, with a little albite or orthoclase and chrome-iron (small black specks, not estimated), 39.27.

As usual, this number contains several valuable original papers bearing upon astronomy, geology, and natural history.

Journal für Gasbeleuchtung und Wasserversorgung, Nos. 15 and 16, 1871.

These numbers do not contain any original papers besides those specially bearing upon subjects pertaining to gas- and water-works' engineering and management.

Annales des Mines, Nos. 5 and 6 (double number), 1870.

The original papers contained in this number do not treat on subjects related to chemistry or allied sciences.

Nos. 1 and 2 (double number), 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

Essay on Red-Lead, or Minium, and a New Method of Preparing it.—G. Mercier.—This paper, illustrated by engravings, describes a series of experiments made on the large scale with the view to obtain a more rapid, less expensive, and less tedious method whereby massicot may be converted into red-lead.

Note on the Use of Nitro-Glycerine in the Working of Marble Quarries of the Valley of La Vire, near Saint Lô, La Manche, France.—H. Harlé.—This paper contains an account of the preparation of nitro-glycerine on the spot where it is to be used for blasting purposes in quarries or mines; it appears that, in this way, the use of nitro-glycerine has become very prevalent in mining operations in the country above named.

Exhaustive Essay on the Various Explosive Substances Used in Mining Operations.—A. Henry.—This essay contains the following sections:—Elements of the comparative value of the different explosive substances used in mining operations—viz., gunpowder, guo-cotton, nitro-glycerine, dynamite, duoline, and lithofracteur; mode of applying these materials, and results obtained therefrom in practice; on conditions of safely manufacturing, carrying, and warehousing blasting-powder; conclusions. This important essay is illustrated by engravings.

Memoir on the Siebengebirge and the Eifel.—R. Zeiller.—A geologico-metallurgical monograph, illustrated by maps and charts.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, July, 1871.

This number only contains the two following original papers relating to physico-chemical sciences:—

Formation of the Anhydrite met with along with Rock-Salt. G. Rose.—This exhaustive chemico-mineralogical monograph does not admit of any useful abstraction. As is usual with the eminent author, this essay testifies to his high accomplishments and excellent method of research.

Electrical Oscillations Observed in Rectilinear Conductors after the Opening of a Collateral Current.—Dr. J. Bernstein.—Illustrated by woodcuts and several tabulated forms.

Journal de Pharmacie et de Chimie, June, 1871.

This number contains the following original papers and essays:—

Researches on the Products of the Oxidation of the Principal Normal Alcohols.—J. Pierre and E. Puchot.—This lengthy essay contains the following sections:—Introduction, treating on the principal products of oxidation of normal alcohols in general; preparation of the myric valerinic acid, $C_{11}H_{22}O_4$, $C_{10}H_{20}O_4$, by the oxidation of amylic alcohol; preparation of the butyric butyrate, $C_4H_7O_2$, $C_4H_9O_2$; preparation of propylic propionate, $C_3H_7O_2$, $C_3H_9O_2$.

Electrolysis of Phthalic Acid.—E. Bourgoïn.—This essay contains the description of the result of a series of experiments instituted by the author, with a view to ascertain the effect of electricity upon phthalic acid and its salts. The acid is decomposed, the reaction being represented by the following formula:—

at the positive pole, $(C_{10}H_4O_4 + O_2) + H_2O_2 = C_{10}H_8O_8 + O_2$. Solution of neutral phthalate of potassa, reaction:—

Phthalate of potassa and free alkali; this mixture behaves exactly as the neutral salt.

General Conditions of the Production of the Phenomena of Incandescence; Origin of these Phenomena.—A. Boillot.—This essay treats exhaustively on the phenomena of combustion in a wider sense, including the spontaneous and sudden decomposition of such substances as anhydrous nitric acid, chloride of nitrogen, iodide of nitrogen, and nitro-glycerine. The author reduces the phenomena alluded to simply to "mouvement de la matière," that is to say, the succession of the different positions a body takes up.

On Iodated Cotton.—C. Méhu.—The contents of this paper bear upon the properties and preparation of a pharmaceutical compound of cotton wool, impregnated with 5 per cent of iodine, and employed for external use.

Polytechnisches Journal von Dingler, second number for July, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Gold-Ruby Glass.—W. Müller and Dr. F. Knapp.—This very exhaustive memoir treats on that kind of glass which owes its beautifully red-purplish colour to gold. The first portion of this monograph contains a review of the literature of the subject alluded to, and of the various theories and opinions held on the condition of the gold while acting as a pigmentary or staining matter. The other sections are the following:—The gold—from this part of the memoir it appears that the quantity of gold required to impart colour to the glass mass is very small indeed, since 1 part of gold in 100,000 of the metal (as the molten glass mass is technically called) distinctly yields a rose-red colour; influence of the composition of the glass mass; influence of temperature and of the length of time taken by the smelting of the glass mass; influence of the so-called glass gall; influence of the cooling; colours of gold-stained glass and the variations thereof; the annealing; constitution of the gold-containing glass. The authors did not succeed in discovering by experiments what the condition is of the gold in the glass; the chief reason of this failure is that the quantity of gold is infinitesimally small.

On Nickeling and Cobalting by the Wet Way.—Dr. F. Stolba.—The author's process, described at great length, is based upon the fact that nickeling and cobalting by the wet way (that is to say, the coating of other metals with a more or less thick film of either nickel or cobalt) succeeds by using along with either a solution of or the dry salt of nickel, chloride of zinc in dilute solution, metallic zinc, and some pure hydrochloric acid.

Cleaning Glass Vessels wherein Petroleum has been Kept.—Dr. F. Stolba.—Thin milk of lime, used for washing glass vessels wherein the liquid alluded to has been kept, forms with the petroleum an emulsion, and renders it possible to remove any traces, and, by the addition of a small quantity of chloride of lime to a second washing with milk of lime, even the smell so completely as to render the vessels so cleaned fit for pouring and keeping beer therein; if warm milk of lime be used, the operation, which otherwise takes considerable time for completion, is rendered shorter.

Detection of Woody Fibre in Paper.—Dr. J. Wiesner.—A microscopic-technical paper. By the proper application of the microscope, the author finds that not only can woody fibre be detected in paper, but even the kind of wood recognised which has been pulped.

Description of an Apparatus suited for Exhausting Oil Seeds by means of Canada Oil (Petroleum Spirit) for the Preparation of Oils to be Used as Food and other Purposes.—Dr. H. Vohl.—Illustrated by engravings.

Comparison of the Relative Value of Canada Oil and of Sulphide of Carbon for the Purpose of Extraction of Oils from Seeds.—Dr. H. Vohl.—The sp. gr. of well-refined Canada oil = 0.68; that of purified sulphide of carbon = 1.265. 100 litres of the former liquid weigh 68.0 kilos.; the same quantity of the latter weigh 126.5 kilos. While, abroad, the price of 100 litres of the Canada oil is such that, as compared with the same bulk of sulphide of carbon, the former liquid costs 8 thalers 29 sgr. less than the latter (the thaler is equal to 3 shillings, the silbergroschen is equal to about 1 penny).

Composition of a Dressing (Weaver's Glue) to be Applied to Calico Fabrics, and Obtained from France.—Dr. T. Finckh.—The author's aim in testing the dressing was to find out the best means of preparing it for use, the result being that 2 parts of caustic soda are used along with water to saponify from 4 to 5 parts of palm oil; to the resulting soap immediately sufficient hot water is used to dissolve it, and next 30 parts of glycerine (sp. gr. = 1.214) are added to the yet hot fluid. After cooling, 8 parts of wheat starch are stirred through the fluid, which is next brought up with water to weigh 100 parts. A small quantity of carbolic acid is added to prevent fermentation of this mixture, which should be kept in a cool place, and not made up in too large quantity at once; for use as dressing, to 100 lbs. of potato-starch from 6 to 8 lbs. of this mixture are taken.

Easy Method of Testing Soft, or Potassa, Soaps for the Quantity of Oil or Fat and Alkali Contained therein.—Dr. U. Grüger.—Reserved for full translation.

Notes on Ultramarine.—C. Fürstenau.—Microscopical research of the pigment alluded to proves that it is not a homogeneous mass, but contains:—(1) A blue-coloured glass-like sintered mass; (2) deep blue-coloured grains of unequal size, the larger of which exhibit a white-coloured nucleus; (3) unacted-upon kaolin; and a colourless camel-like substance. The last-named materials were found by the author in all kinds of ultramarine, even of the best makers.

Strong Vegetable Glue.—A. Sella.—This preparation is a mixture of nitrate of lime, water, and pulverised gum, in the proportion of 2, 25, and 20; the solution of the nitrate of lime contains 33·3 per cent of that salt. This glue may be used for glass, porcelain, wood, cardboard, marmor, &c.

Les Mondes, September 7, 1871.

The original papers and essays, relating to chemistry and allied subjects, met with in this number are the following:—

Dry Distillation of Wood.—M. Maiche.—From this lengthy paper, written by a practical distiller of wood, we quote the following particulars:—This industry does not pay unless the greatest care is taken to utilise advantageously all the products, which, for 100 kilos. of wood submitted to distillation, amount to 50 kilos. of raw produce, wherein are contained: Methylic alcohol, 2 kilos.; crystallisable acetic acid, 3 kilos. (i.e., that quantity of glacial acetic acid may be obtained); tar, 10 kilos.; water, 35 kilos.; and a residue of charcoal, weighing 22 kilos. Dry wood, submitted to distillation at 700°, yields, among other products, an oil which, like paraffin oil, can be used in lamps; it boils at 90°, and is devoid of smell. The author has also tried, as yet only on a small scale, to submit chopped-up wood to distillation in water containing to per cent of sulphuric acid; the result is the formation of acetic acid very abundantly, and of a peculiar aromatic principle insoluble in cold water.

Notes on the Mineral Statistics of Italy.—M. Giordano.—This paper, from the hand of the Chief Inspector of Mines for the kingdom just named, contains information on the extraction of sulphur (by far the most important of the Italian minerals); iron ores and the iron manufacture; copper, lead, and zinc ores, which are exported chiefly to England and Belgium, owing to the fact that Italy lacks mineral fuel; gold, of which annually about 400 kilos. are obtained; and, lastly, an account of the engineering establishments of Italy.

September 14, 1871.

Among the original matter contained in this number the following relates to chemistry and collateral sciences:—

Ammonia Engine.—C. Tellier.—An account of the mode of action and principles of the application of ammoniacal gas instead of steam for the purpose of imparting motion to machinery. This application is based upon:—(1) The great solubility of ammoniacal gas in water; (2) the facility of liquefying that gas; (3) the fact that at ordinary temperatures the gas exerts a pressure sufficiently strong to be industrially applied; (4) the possibility of superheating ammoniacal vapours without a too high temperature; (5) the fact that the gas can be dissolved in water and recovered and again applied for use.

Exposition of an Economical Method of Application of Steam.—M. Autier.—Although not exactly belonging to the subjects usually treated of in our pages, we call attention to this subject, which is here treated of in the shape of a review of a book, the chief theme of which is cheap motive force with all kinds of fuel. It appears from the *résumé* here published that the author, a practical engineer, is well up to his subject, which entails economy of construction of engines and boilers, economy of fuel and labour, and a decrease of wear and tear.

Elements of Organic Chemistry.—Dr. Sacc.—Attention is here called to this work, recently published at Paris by Lacroix. From the preface of this book it appears that the author's aim has been to produce what he terms "Première Tentative d'une Chimie Naturelle et Pure." The excellent editor of *Les Mondes* speaks highly of the volume, which is sold at 2s. 6d., and contains 478 pages.

September 25, 1871.

This number does not contain any original papers relating to chemistry and collateral sciences, but we call attention to a paper:—

On Portable Tramways for Agricultural Use.—M. Corbin.—Illustrated by engravings. The contrivance is intended especially to facilitate the removal of root-crops from the field, by a rapid and very cheap method of conveyance which can be applied everywhere.

Hints for the Proper Arrangement of Meteorological Observatories.—V. Regnault.—Illustrated by engravings.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, September 7, 1871.

This number, the first of a new volume, opens with an excellent preface which, undoubtedly, proves that "La France intelligente, éclairée, et libérale ne périt pas, et n'est nullement éteinte." The following original matter is met with in this number:—

Chenot's Process of Iron and Steel Manufacture.—C. Mène.—The author describes at length a mode of manufacturing iron by which the metal is obtained in a spongy state instead of being smelted. The operation is conducted in peculiarly arranged furnaces, the ore being first calcined. The spongy metal is next converted into steel by being first soaked in either molten resin, coal-tar, or other suitable similar substance, and then calcined. The carbonated spongy mass is next ground to powder, and having been placed in moulds, is very

strongly compressed, after which the solid lumps are put into crucibles and fused. It appears from experiments made on the large scale at Clichy, that the iron thus obtained (no mention is made of the nature of the reducing agent employed) is superior in every respect to that produced by blast furnaces; as to the cost of this process nothing is mentioned, but, since cast-steel of excellent quality, or malleable, or, if desired, cast-iron, can be produced at will, and the operation of puddling and refining are dispensed with, it is probable that the expense will not exceed that of the usual process, while the yield of metal from the ore is stated to be in favour of Chenot's process, by which phosphorus and sulphur are also eliminated.

Apparatus for Exhibiting the Phenomena of Cooling Water far below its Freezing-Point and the Effects of its Expansion on Freezing.—F. Hamel.—The description, accompanied by a woodcut, of a neat and highly instructive apparatus made by M. Alvergnat, Passage Sorbonne, Paris.

Description of Foucault's Heliostate, Constructed by J. Duboscq, Rue de l'Odéon, Paris.—C. Mène.—Illustrated by a woodcut.

Studies on the Chemical Dissociation of Bodies.—C. Mène.—The first portion of a well and clearly written essay on this subject.

NOTES AND QUERIES.

Electro-Deposition—Crimson Spirit.—(1). Can any of your readers tell me of a good practical method of depositing bright platinum on iron or copper? (2). Can aluminium be anyhow deposited by the battery? (3). How can I make "crimson spirit" used by silk dyers?—INQUIRER.

Electrical Phenomena.—A few days ago I stood near a person cleaning windows; I noticed that, after wiping the glass with a wet leather, she used an old silk handkerchief as a duster to dry the pane. I also noticed that while the glass was being rubbed with the silk a crackling sound emanated from the pane. Taking notice of this circumstance I waited till the evening, when it was perfectly dark, and repeated the experiment thus:—In the first place, I took a pane and rubbed it with the handkerchief, and I thus obtained a number of flashes of light with crackling accompaniment. I then rubbed the pane with the wet leather, and again rubbed with the silk; the flashes and noise were both more decided than before, the former being very bright; with prolonged rubbing they gradually died away, but on rubbing again with the leather, and afterwards with the handkerchief, they again became bright and more copious. I repeated the experiments with different panes and on three different windows successfully. The kind of electricity is positive, as that of dry glass and silk. The experiments were conducted out of doors, and the weather at the time was cold, with a slight mist in the atmosphere. I have tried the experiment with a cotton instead of a silk duster with nearly equal success. The experiments have been repeated on subsequent evenings, sometimes successfully, and sometimes not, the former predominating over the latter. I have sent this notice of the above, because I have not yet seen a description of anything similar, and because it seems to prove that absolute dryness is not indispensable to electrical experiments, and to show that it is unnecessary to roast the apparatus to death, as is the common practice of some lecturers.—W. JESSA LOVETT.

TO CORRESPONDENTS.

D. R.—It will be better to keep the solution boiling or nearly so the whole time of passing the gas.

W. H.—Several kinds of laboratory-labels have been noticed in our columns; they have also been advertised in this journal.

J. P. Barnett, New York.—Wormley's "Micro-Chemistry of Poisons" is the only book we know of which treats on the subject.

BOOKS RECEIVED.

Flint. A paper read before the Geologists' Association, June 2nd, 1871. By M. Hawkins Johnson, F.G.S.

The Journal of the Iron and Steel Institute, vol. ii. London: E. and F. N. Spon.

Miscellanies. By John Addington Symonds, M.D. Selected and Edited, with an Introductory Memoir, by his Son. London: Macmillan and Co. Bristol: J. Arrowsmith.

On the Relative Powers of Various Substances in Preventing the Generation of Animalculæ or the Development of their Germs, with special reference to the Germ Theory of Putrefaction. By John Dougall, M.D. Glasgow. London: J. and A. Churchill, New Burlington Street.

Sixth Report of the Quekett Microscopical Club, and List of Members. On the Economical Production of Peat and Peat-Charcoal. Liverpool: Peat Engineering and Sewage Filtration Company.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE
QUARTERLY JOURNAL OF SCIENCE,
AND
ANNALS OF MINING, METALLURGY, ENGINEERING, INDUSTRIAL ARTS,
MANUFACTURES, AND TECHNOLOGY.

Edited by WILLIAM CROOKES, F.R.S., &c.

Now ready, No. XXXII., October, 1871, price 5s., Illustrated.

CONTENTS.

London: Offices of the Quarterly Journal of Science, 3, Horse-Shoe Court, Ludgate Hill, E.C.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations. Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations. Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations. Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s. Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND CO., 20, King William Street, Strand.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871-1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock. Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily. Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience. Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HICKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

TECHNICAL EDUCATION.

SCIENCE and ART DEPARTMENT.

Royal College of Science for Ireland, STEPHEN'S GREEN, DUBLIN.

SESSION—1871-72.

This College supplies, as far as practicable, a complete Course of Instruction in Science applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

There are Four Royal Scholarships, of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in College. There are also Nine Exhibitions attached to the College, of £50 each, with Free Education and Laboratory Instruction, tenable for three years. Three become vacant each year. These are awarded at the Annual May Examinations of the Science and Art Department.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory.

The Laboratory Fee is £12 for the full Course of nine months, or £2 per month.

SUBJECTS OF INSTRUCTION.

Applied Mathematics, Mechanism and Machinery, Descriptive Geometry, Geometrical, Mechanical, and Engineering Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology and Palaeontology, Mining, Surveying, Agriculture.

The Laboratory is open for Instruction in Practical Chemistry, Metallurgy, and Assaying, from ten to four o'clock every week-day during the Session, except Saturdays and Holidays.

The Session commences on MONDAY, OCTOBER 2. Programmes may be obtained on application to the Secretary Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

THE CHEMICAL NEWS.

VOL. XXIV. No. 620.

NOTE ON A NEW SCOTCH ACIDULOUS CHALYBEATE MINERAL WATER.

By JAMES DEWAR, F.R.S.E.

It is generally known that this country is extremely deficient in well-marked chalybeate waters. Plenty natural waters, containing small proportions of iron, are to be met with in the United Kingdom; but, with the exception of those of Tunbridge Wells, Harrogate, Sandrock (Isle of Wight), Heartfell, near Moffat, and Vicarsbridge, in the vicinity of Dollar, they contrast very unfavourably with those of the numerous spas of the continent of Europe. If we restrict ourselves to an examination of the chemical characters of the above-mentioned Scotch chalybeates, we observe that the iron is present in large quantities in the form of sulphate, along with sulphate of alumina, on which account they are more nauseous to invalids, and are at the present time rather unpopular.

Recently my brother, Dr. Alexander Dewar, Melrose, sent me for analysis a sample of a new well water, whose peculiarity had previously attracted his attention. A chemical examination of the water in question showed it to be a well-defined acidulous chalybeate, unusually rich in carbonate of iron. The following are the analytical details. (As the surface-water gets access at present, a very exhaustive analysis appeared unnecessary):—

	Grains per gallon.
Carbonate of iron	17.5
Alumina	1.8
Silica	8.5
Sulphate of magnesia	7.8
Chloride of calcium	16.0
Carbonate of calcium	4.1
Alkaline chlorides	11.4

67.1

Carbonic acid gas per gallon 40 cubic inches.

With the exception of the celebrated "Dr. Muspratt's chalybeate," at Harrogate, which contains 10.8 grains per gallon of carbonate of iron, along with 16.0 grains of protochloride, I do not know of any natural water in this country containing such a large proportion of iron in the form of carbonate. And it is to be observed that the water is not associated with a large quantity of other salts.

The well whence the foregoing sample was taken has not been long sunk, and its water is perfectly different from all of those in its immediate vicinity. Should it maintain its present character, I have no doubt that, judging from its own qualities, as well as from its favourable climatic situation, along with the general interest attached to the locality, this chalybeate is certain to recommend itself to the medical profession.

ON THE ESTIMATION OF SULPHUR BY BARIUM.

By E. F. TESCHEMACHER and J. DENHAM SMITH.

WE have read the remarks of Messrs. Nicholas Glendinning and Alfred Edger, in the CHEMICAL NEWS, on the "Estimation of Sulphur by Barium."

In our memoir on this subject we pointed out that when a boiling solution containing sesquioxide of iron, sulphuric acid, and a large excess of hydrochloric acid was precipitated by chloride of barium, and the resulting sulphate of

barytes washed by moderately strong and hot hydrochloric acid, and finally, by boiling water, there might sometimes be observed on the sides and bottom of the beaker containing the filtrate and washings, after these had cooled and been allowed to stand for several hours, a film, which film we stated to be sulphate of barytes; adducing this observation as one proof amongst others of the solubility of sulphate of barytes in hot and moderately strong hydrochloric acid.

Now, the very first statement Messrs. Glendinning and Edger make, after announcing that they differ from our conclusions, is, "We attribute this (film?) to sulphate of iron" (*sic in orig.*).

In the face of the absurdities involved in this quotation, and the proof it affords of the incompetency of its authors, our would-be critics, to deal with any question of analytical chemistry, we take leave to decline following them through the opinions, contradictory statements, and unproved assertions which compose the rest of the remarks of these somewhat hazy writers of Newcastle-on-Tyne.

NOTES ON THE COLOUR OF FLUORESCENT SOLUTIONS.

By Professor HENRY MORTON, Ph.D.,
President of the Stevens Institute of Technology, N.J.

II.

I HAVE recently observed a curious action, which while it in no respect affects the general conclusions given in the CHEMICAL NEWS (vol xxiv., p. 77), nor the main observations on which they were founded, throws out the corroborative experiments by which I thought that they might be established when a spectroscope was not at hand.

Obtaining some very anomalous results of late, I was led to mistrust the action of the Geissler-tubes in which the solutions had been examined. These were of the ordinary kind of jacketed spirals, selected as being nearly identical in size and other particulars.

It had been observed from the first that the internal spiral gave a faint blue fluorescence, which could only be seen on close inspection, and in all cases the tube being but partly filled, it was considered that a light appearing in the part covered by the fluid, many times more bright than that from the uncovered part of the spiral, was sufficient evidence of fluorescence in the liquid.

Late experiments have, however, proved that this was not so. Any liquid, however devoid of fluorescent properties, gives all the appearance of fluorescing in these tubes, and on a little thought the cause of this became clear.

The only fluorescent light that can be seen from the glass of the spiral is that which comes off tangentially, the foreshortening increasing its effect, while from the outer surface, that emitted radially is masked by the bright electric discharge behind.

In passing from the glass to air most of this light will suffer total reflection at the outer surface of the glass, but if water or any other liquid is substituted for the air, its greater refracting power (approaching that of glass) will diminish the above-named action, so that much more of the light will reach the eye. The truth of this explanation was supported by the observation that the nearer the index of refraction in the liquid came to that of glass the brighter was the light seen through it.

This fact renders of no account the observations before made on filtered and diluted solutions of turmeric, but a fresh observation with the spectroscope on tubes free from fluorescence, has fully confirmed my former conclusions as to the true colour of fluorescence in this liquid.

No correction need be applied to the description already published in the case of the asphalt solution, but I may add to what was there stated another striking example.

If one of the little Geissler-tubes containing nitrogen, called spectrum-tubes, be jacketed by means of a perforated cork and a large glass tube, and the jacket filled with pure or non-fluorescent benzene, then illuminating the tube, and with a pipette dropping in that petroleum product called "cosmoline," a lubricating oil made by E. F. Houghton, of Philadelphia, each drop will appear of a rich blue as it dissolves in the benzene, which soon acquires a magnificent blue fluorescence. Increasing, however, the quantity of the cosmoline oil until its colour begins to take effect, the tint of the fluorescence gradually changes to a rich green. By a little care a blue solution may be superposed on a green one in the same tube.

Mr. Houghton informs me that this "cosmoline" is prepared by concentration from crude petroleum at low temperatures by the aid of a vacuum, accompanied by filtration through animal charcoal, by which colour and odour are removed.

Another semi-solid preparation of cosmoline which has a very light colour gives a solution with benzene fluorescing of a magnificent blue.

Returning to the solutions of turmeric, I have found that the fluorescent body in that substance is not its essential oil nor its brown colouring matter, but either the yellow colouring matter itself or something so closely allied to it in solubility that I have thus far been unable to effect any separation.

In connection with this, I am much indebted to Mr. Robert F. Fairthorne, of Philadelphia, who has aided me greatly in the preparation of the various constituents of turmeric in a state of purity.

In my former paper I mentioned that uranium nitrate in solution gave a very faint fluorescence. This appearance, I now find, was due entirely to the above explained action of the tube, and a number of carefully conducted observations now convince me that this substance, while it fluoresces so vividly in the solid state, loses that property entirely when in solution.

DETERMINATION OF COPPER, NICKEL, AND ZINC BY THE BATTERY.

By J. M. MERRICK, S.B.

(Continued from p. 101).

THE amount of zinc contained in the double sulphate of zinc and ammonia was next determined.

The sulphate was made with utmost care, and well crystallised.

The crystals were weighed in the platinum crucible, dissolved in hot water, the solution supersaturated with ammonia, and subjected to the action of a comparatively feeble galvanic current.

If too strong a current be used, the deposit will become flaky or spongy, and very difficult to wash and dry unoxidised. This was the case in the second determination below, which accounts for the comparatively large error.

The deposit of zinc was washed with water first, then with alcohol, and very carefully dried and weighed.

(f). 0.5443 grm. ammonio-sulphate of zinc gave 0.088 grm. metallic zinc = 16.16 per cent.

(m). 0.815 grm. ammonio-sulphate of zinc gave 0.133 grm. metallic zinc = 16.31 per cent.

In this case, as explained above, the deposit was spongy, and probably oxidised a little.

Theory.	l.	m.
16.20	16.16	16.31

Some determinations of copper in the purified and re-crystallised sulphate were also made with the following results, viz.:-

(n). 0.77 grm. sulphate of copper gave 0.1959 grm. metallic copper = 25.44 per cent.

(o). 0.79 grm. sulphate of copper gave 0.2013 grm. metallic copper = 25.46 per cent.

Theory.	n.	o.
25.46	25.44	25.46

The atomic weight of copper is here taken at 31.75.

The following determinations were made with larger amounts of the salts, and in a large platinum dish.

(p). 1.0075 grm. double sulphate of nickel and potash gave 0.1334 grm. metallic nickel = 13.24 per cent.

(q). 0.3922 grm. double-sulphate of nickel and potash gave 0.5286 grm. metallic nickel = 13.45 per cent.

(This determination may fairly be thrown out, as the battery was allowed to run all night, and the nickel on the edges of the liquid had a chance to oxidise, and thus increase the apparent percentage up to 13.45).

In the following determination the large dish used was counterbalanced to within 2 grms. by platinum crucibles, and abundant time allowed in every weighing for the platinum vessels on each scale to condense the amount of moisture proper to the temperature of the balance case.

The balance used is one of Becker's make, turning readily with 0.0001 grm. when loaded with 55 grms. in each pan; but even this is, I am confident, not delicate enough for the perfectly accurate determination of small quantities of metals by the galvanic method.

(r). 1.7857 grms. double phosphate of nickel and potash gave 0.2369 grm. metallic nickel = 13.27 per cent.

Theory.	p.	q.	r.
13.29	13.24	13.45	13.27

It will be observed that in this method of determination the metal is weighed *as such*; that is, we have no assistance in our work from an increased atomic weight, as *e.g.*, when sulphur is determined as sulphate of baryta, and, consequently, the utmost care is required in weighing. In every case, for exact work, the platinum dish should be balanced as near as may be by one of equal size. The metallic deposits should be washed with alcohol, dried very cautiously, and the plated dish allowed to stand on the balance at least ten minutes before its weight is taken. In this way, and by using for the work an only moderate battery power, I believe determinations can be made whose exactness and nicety will depend on the delicacy of the balance employed.

Indeed, I see no reason to doubt that, with a sufficiently delicate balance, the results will not vary much in the third decimal figure, and I believe it is by this process that the atomic weights of copper, nickel, and cobalt will finally be settled.

Laboratory, 59, Broad Street, Boston, Mass., U.S.

CONTRIBUTION TO OUR KNOWLEDGE OF THE COLOURING MATTER CONTAINED IN COCHINEAL.

By C. LIEBERMANN and W. A. VAN DORP.

IN order to judge of the constitution of the colouring matter of cochineal we considered it best first to investigate the nature of the nitrococcic acid, as being the most thoroughly known product of the decomposition of the colouring matter alluded to.

The acid just mentioned is formed by the action of nitric acid upon the colouring matter, while, according to Warren de la Rue, the formula of nitrococcic acid is $C_8H_5(NO_2)_3O_3$. Since this acid, as stated by the author just named, saturates two atoms of basis, it cannot be the nitro-product of one of the isomeric methoxybenzoic acids, but it might be, as suspected by Strecker, derived from a cresotic acid provided the formula (above-mentioned) correctly expresses the molecular size of the acid.

We have found that nitrococcic acid can be obtained readily and in large quantity by employing for its preparation commercial carmine instead of the chemically pure pigment of cochineal, which is difficult to prepare. When finely pulverised, carmine is gradually put into a vessel containing boiling nitric acid (sp. gr. 1.37) as long as the violent evolution of red vapours continues; the whole mass solidifies after evaporation, yielding a mixture of crystals of oxalic and nitrococcic acid, from which the former is removed by re-crystallisation from a very weak nitric acid solution, the latter being obtained in a pure state in the shape of large foliated silvery crystals. On heating the nitrococcic acid along with water to 180° in a sealed tube, there escapes from the latter, when opened after the operation, a considerable quantity of carbonic acid, while at the bottom of the yet warm tube an oily fluid is observed, which, on cooling, solidifies, exhibiting a yellow-coloured crystalline structure; by the aid of water, in which liquid nitrococcic acid is more readily soluble, the newly formed substance is freed from any adhering nitrococcic acid. On further investigation of the yellow-coloured body, it was found to possess the composition of trinitrocresol, $C_7H_4(NO_2)_3OH$, agreeing, as regards its properties, in all respects with the trinitrocresol obtained by Duclos from coal-tar cresol. The trinitrocresol obtained by us, as just mentioned, fuses at 104°, and its potassa salt, $C_7H_4(NO_2)_3OK$, crystallises from an aqueous solution, exhibiting yellow coloured, needle-shaped crystals.

Nitrococcic acid is, consequently, one of the isomeric trinitro-cresotic acids, but, since these have not been hitherto obtained from any of the now-known cresotic acids, it is not possible by comparison to decide from which of these acids it is derived. The dissociation of nitrococcic acid by the action of water takes place according to the following formula:—

The same kind of dissociation takes place when nitrococcic acid is heated along with pure hydrochloric acid to 180°; no substitution of the nitro-group by chlorine takes place.

From the formation of cresol from nitrococcic acid, we conclude that the colouring matter of cochineal contains methyl groups to which remnants of benzol (*benzolreste*) unite. In order to protect that portion of the molecule of carmine which, by the action of nitric acid, becomes nitrococcic acid, from the oxidising and nitrating influence of that acid, we have tried to bring about a dissociation of the pigment by means of concentrated sulphuric acid.

When a solution of carmine in concentrated sulphuric acid is submitted to heat, the yellowish-red colour of that solution changes at 120° into violet, while CO_2 and SO_2 are evolved; the heat having been increased to, and kept for some time at, 140° to 150°, there is, by the addition of water to the acid solution, precipitated another newly formed pigment in the shape of a brown-coloured flocculent substance, which, having been collected on a filter, well washed, and next dried, and then treated with boiling alcohol, leaves, on evaporation of that menstruum, the new body which we term *rufiococcin*, difficultly soluble in cold water, and thereby distinguished from carminic acid and carmine-red, soluble in alcohol, exhibiting a magnificent yellow fluorescence. This substance is, to some extent, sublimable, giving off red fumes, and solidifying in needle-shaped yellowish-red crystals. Previously mordanted textile fabrics are dyed by this pigment similar to cochineal, but the dyes are less brilliant; upon being analysed, the formula of this body was ascertained to be $C_{16}H_{12}O_6$.

Considering the origin and reactions of rufiococcin, and finding these to be very nearly analogous to rufigallic acid and the opianic acid pigment, $C_{14}H_8O_6$, derived from anthracene, we do not doubt that it (the rufiococcin) contains the complex of dimethylantracene, and that, we

think, the constitutional formula of the former mentioned substance is—

The origin of rufiococcin can be readily explained when it is assumed that two molecules of the substance which, by nitration form nitrococcic acid, join with elimination of water.*

The behaviour of rufiococcin with zinc dust confirms our view just expressed, for by the action of that metal rufiococcin yields a hydrocarbon akin to anthracene, which new hydrocarbon fuses at a high temperature, and sublimes, forming a white foliated matter, which combines with picric acid, yielding a red-coloured combination. The hydrocarbon alluded to fuses at 100°, but we have not analysed it as yet, being desirous to obtain it in larger quantity first. The formula found by us for rufiococcin is closely the same as that which Hlasiwetz and Grabowsky have found for coccinin obtained by the dissociation of carmine-red under the influence of fusing caustic potassa; coccinin behaves as a hydrochinon of rufiococcin, since, after its (the coccinin's) spontaneous oxidation by contact with air, it exhibits the same colouring phenomena as rufiococcin does. The fact that by the fusion with caustic potassa the reduction product is formed agrees with the analogous behaviour of anthrachinon; Hlasiwetz and Grabowsky have observed that along with coccinin succinic acid was formed. Although these chemists ascribe the formation of that acid to the decomposition of a glucoside sugar, it is, according to newly-made discoveries by Baeyer on pigments, and considering the similarity of the cochineal pigment with the pigments contained in some kinds of dye-wood, not quite impossible that carmine-red is either a derivative of succinic acid, or from an acid which, by fusing with caustic potassa, is converted into succinic acid.—*Berichte der Deutschen Chemischen Gesellschaft zu Berlin.*

NOTE ON PURE CARBOLIC ACID.

By Professor CHURCH, M.A.

SINCE 1856 I have occupied myself a good deal with experiments as to the practical hygienic applications of carbolic acid, particularly as to its use in dentistry and in throat affections, and also as regards its employment as a disinfectant. The rank of carbolic acid as a most valuable contribution from chemistry to medicine is so well assured that it is unnecessary to insist upon this point here. Yet there is an objection urged against this substance, which has some apparent force, simply because the best preparations of commerce are so seldom free from a gas-like or naphthalic odour, which, though entirely foreign to carbolic acid itself, has condemned its use in some quarters. About 11 years ago, in preparing pure carbolic acid for the use of a surgeon-dentist to whom I introduced it, I adopted a plan which I shortly afterwards described before the Odontological Society, and to which I have been lately asked to give greater publicity. My plan, which is very simple, is as follows:—

One pound of the best carbolic acid of commerce (I use Calvert's white crystallised acid) is poured into 20 pounds

* The fact that this compound contains 1 atom of oxygen more than the cresotic acid, the mother or parent substance (*Muttersubstanz*) of the nitrococcic acid, is explained by the observation that, by the dissociation of the cochineal pigment by nitric acid, the gap, or breach rather, made by the dissociation is filled by NO_2 , while, in the case of the dissociation by sulphuric acid, the breach is filled by OH.

† These will be published in our columns at a future date.

of cold distilled water, taking care not to permit the *whole* of the acid to enter into solution. With a good sample, if after shaking repeatedly at intervals, between two and three ounces of the acid remain at the bottom of the vessel used, this will be a sufficient residue to hold and contain all the impurities. With bad samples, less water must be used or more acid. The aqueous solution should be syphoned off, and filtered if necessary through Swedish paper till perfectly clear; it is then placed in a tall cylinder, and pure powdered common salt added with constant agitation till it no longer dissolves. On standing the greater part of the carbolic acid will be found floating as a yellow oily layer on the top of the saline liquor, and merely requires to be removed by a syphon or pipette to be ready for use. As it contains 5 per cent or more of water, it does not generally crystallise, but it may be made to do so by removing it to a retort, and distilling it from a little lime. The portion collected up to 185° C. or thereabouts has at ordinary temperatures scarcely any odour, save a faint one resembling that of geranium leaves; and I have taken advantage of this curious resemblance still further to mask the slight smell proper to absolutely pure carbolic acid by the addition to it of four drops per fluid ounce of the French oil of geranium. This addition has the further advantage of liquefying the pure crystallised product.

The carbolic acid purified as above has been so highly appreciated by those professional and private persons to whom I have distributed samples, and who were dissatisfied with the purest commercial samples, that I have thought it best to publish my simple plan, for which, however, I claim no originality. It involves, I know, considerable loss of material, but the saline liquor remaining may be distilled and thus made to yield up a second portion of pure carbolic acid, and it will be found a very pleasant and effective domestic disinfectant and deodoriser.

When dissolved in 230 parts of water and used as a gargle, or in 25 parts for painting the throat, or in 50 parts for a carbolic spray, the pure acid is rarely, if ever, objected to even by the most fastidious person. Of course it may be readily mingled with olive or other oil ($r : 25$) or with glycerine, for dressing cuts and sores, and when introduced into the little air-purifier invented by me and noticed in your columns some months back, diffuses wholesome and inoffensive vapour in any place where there are disagreeable effluvia of vegetable or animal origin.

THE GASES FROM THE BESSEMER CONVERTER.

By W. MATTIEU WILLIAMS, F.C.S.

MR. Snelus, in his paper printed in the last number of the *CHEMICAL NEWS*, disputed my supposition that the brilliancy and whiteness of the Bessemer flame, especially in its latter stages, may be partially due to the combustion of hydrocarbons, the basis of his conclusion being that he does not find any hydrocarbons by the means he has adopted for collecting the gases.

I never supposed that he would find any hydrocarbons there, for the simple reason that they must be oxidised before they reach the mouth of his collecting tube. He might as well dispute the combustion of carbon because he finds no uncombined carbon in the same place. If I am right, he should find not hydrocarbons, but the products of hydrocarbon combustion, viz., carbonic acid, carbonic oxide, and water. He has looked for and found the two former, but has altogether omitted the consideration of the water.

In consequence of this omission, his investigations throw no new light upon this question, but leave it exactly where he found it. He does not tell us whether any deposition of moisture could be obtained by cooling down his sealed collecting tubes, or anything else concerning the hydro-

metric condition of the gases they contained. All the analyses stated by Mr. Snelus make up exactly the 100 parts without any loss. Did he dry his gases before making these analyses, and if so, how much did they lose in drying? If they were dry already, what became of the water originally contained in the atmospheric air used for the blast?

In asking these questions I am not finding fault with what Mr. Snelus has done, but, on the contrary, regard his work as an important contribution to our knowledge on this subject. My object is simply to show that further investigations are necessary before the question which I raised respecting the hydrocarbons can be answered either way.

My reasons for suspecting that hydrocarbons are burning in the Bessemer flame are—that the so-called “carbon spectrum” which it exhibits is far more complex than the carbon spectrum proper; that the colour and general appearance of the flame is quite different from that produced by the combustion of simple carbon or carbonic oxide under such circumstances; that the spectrum is more like a hydrocarbon than a simple carbon spectrum; that the flame presents exactly the appearances we can obtain by artificially mixing carbonic oxide and hydrocarbon (coal-gas for example) in certain proportions; and, further, that in the Bessemer converter during the blow we have the materials and conditions which, theoretically, should produce such an admixture of hydrocarbon and carbonic oxide.

I protested against the looseness of describing the Bessemer spectrum as a “carbon spectrum” on the ground that each compound of carbon affords its own special spectrum, and that the Bessemer spectrum is one of these compound spectra, and I directed the attention of spectroscopists to the interesting practical questions relative to the state in which carbon exists in steel which the study of the Bessemer spectrum might help to solve if it could reveal the composition of the Bessemer flame. My paper was written before Dr. Watts's recent investigation on this subject were published. These have, in a great measure, removed the objections I made to the previous spectroscopic investigations of the Bessemer flame.

In examining this subject we must always remember that we are not dealing with an ordinary hollow flame supplied with oxygen from outside. From such a flame we might, by the method adopted by Mr. Snelus, obtain the combustible gases. The Bessemer flame is quite different. It is supplied by forcing air through *solid* combustibles, some of which yield gaseous combustion products. Mr. Snelus can only thus obtain the gaseous products of combustion by his method, and even though he had looked for water and found it among them, the question of whether hydrocarbons were burning would still remain unanswered. If, however, the spectroscopist can succeed in identifying the characteristic spectrum of the Bessemer flame with that of any particular hydrocarbon, or nitrocarbon such as cyanogen, or a mixture of cyanogen and hydrocarbon, he may throw some light on the much debated question of whether steel is a compound of simply iron and carbon, or iron and a hydrocarbon, and why it is that cyanides and other nitrocarbon compounds are so effective in steel making.

Woodside, Croydon,
Oct. 7, 1871.

NICKEL PLATING AS APPLIED TO PHOTOGRAPHIC PURPOSES.

By JOHN SPILLER, F.C.S.

ABOUT ten years ago, when visiting the bank-note printing establishment of Messrs. Bradbury and Wilkinson, in Fetter Lane, I was shown some nickel-coated plates from which the “nature printing” specimens had been prepared, and had an opportunity of seeing the electro-deposition

of pure nickel upon copper and other metals practically carried out as one of the branches of their printing operations. This process was being applied conjointly with, or as a substitute for, the method of steel facing (*acierage*) of which they are the patentees, and it struck me at once that the permanent quality of the nickel deposit so formed was capable of wider application, and might serve as a means of protecting steel objects from the rusting influence of damp air.

At my suggestion a few steel articles—particularly a dinner-knife, spatula, and split-ring—were coated with nickel, in order to test the degree of protection which such a process would offer when applied to swords, bayonets, helmets, breast-plates, spurs, harness chains, and steel accoutrements generally. The experiment proved perfectly successful, and without prejudice to the colour, and steps were then taken with the view of submitting the idea to the notice of the War Office authorities, particularly as the cost of applying such a process did not appear likely to stand in the way of its general adoption when the great saving of time in cleaning these articles was duly taken into account.

Beyond establishing the fact, no immediate result followed, and from that time to the present year the application of electro-deposited nickel has, so far as I am aware, been restricted to the specific purposes for which Messrs. Bradbury and Wilkinson have continued to apply it in their establishment. Within the last two or three years fresh attempts in my original direction have led to the employment of this process in America, where a patent was taken out for the application, and a company now working under a licence of the American patentees has recently commenced operations in London and Birmingham. I am indebted to the energetic manager of the Plating Company (Limited), Mr. Channer, of 34, Kirby Street, Hatton Garden, for the opportunity of inspecting a vast collection of objects to which the nickel-coating has been applied, and have been furnished likewise with small specimens of copper, brass, and steel coated with the metal in question, by which I am enabled to substantiate the statements made in their prospectus relative to the wonderful degree of protection afforded to the underlying metals by the superficial deposit of pure nickel. I have since had my regulation sword coated at their works, and find it now perfectly secured against rusting in wet weather, and so easily kept in condition that the blade and scabbard require only to be wiped with a washleather, instead of undergoing the tedious process of burnishing, to fit it for appearance on parade.

A small square bar of steel similarly coated has been repeatedly immersed in water for hours together without showing any signs of rusting, and I find it possible to bury it in flowers of sulphur for several days without tarnishing the lustre of the nickel surface. Neither has this latter severe test any effect upon the copper and brass bars upon which the nickel coating has been applied, and these metals may even be immersed in an aqueous solution of nitrate of silver without effecting the reduction of that metal. In one of the angles only, where the coating seems to be imperfect, was there any indication of silver reduction in the case of the brass tube, the steel bar being perfectly protected over the whole surface against the action of silver and copper solutions. Here, then, is a valuable property which I was not led to anticipate in the case of electro-deposited nickel, for I could not have predicted from my chemical knowledge that a metal of the zinc and iron group would be proof against the action of nitrate of silver; but the experiment proves it to be so, and we must regard pure nickel as belonging (from this point of view) to the class of noble metals, resisting, like gold and platinum, the attack of sulphur and of highly corrosive metallic solutions.

The nickel facing when burnished has a whiter colour than polished steel, although not equal to silver itself, its aspect being rather that of rolled platinum. A chemist to whom I showed the specimens pronounced them at once

to be very similar to platinum in regard to colour, thus confirming my own impression on this head. It withstands the action of heat also remarkably well, for the fusion-point is very high, and oxidation occurs only at elevated temperatures. With the view of testing its general applicability to laboratory work I am having a brass scale-pan coated with nickel, and will report later as to its success. For fine balance beams and weights, lens mountings, reflectors, laboratory microscopes, Sykes's hydrometers, still worms, egg beaters, camera fittings, and a variety of apparatus used by the chemist and photographer, the nickel coating will probably find extensive application; and I have seen some oval picture-frames of very pretty effect made from stamped brass coated with nickel. It remains to be mentioned that burnished and matt surfaces of this metal may be used in combination for ornamental purposes.—*The Photographic News*.

ON THE DETERMINATION OF MOLYBDIC ACID AS PLUMBIC MOLYBDATE.

By THOMAS M. CHATARD.

GREAT difficulty has always been experienced in determining molybdenum by any of the methods generally in use. The precipitation as mercurous molybdate, and the subsequent treatment, are both tedious and unsatisfactory, and an accurate determination as sulphide is almost impossible, the filtrate remaining blue even after repeatedly passing sulphydric acid and filtering.

The following method will, I hope, be found to give satisfaction, both as to ease of working and accuracy of results.

Add to the boiling solution of the molybdate, plumbic acetate in slight excess. Boil for a few minutes; the precipitate, at first milky, will become granular and will subside easily, leaving a perfectly clear supernatant liquid. Care must be taken in boiling, as the thick milky fluid is very apt to boil over. A ribbed filter is to be used and the precipitate is to be washed with hot water. The washing proceeds with great ease and thoroughness, and not the slightest milkiness should be apparent in the filtrate. The precipitate is dried at 100°, separated from the filter and ignited in a porcelain crucible.

The results were as follows:—

Grms.	Grms.	Per cent.
1.0744 Na_2MoO_4	gave 1.9176 PbMoO_4	= 46.64 Mo.
1.4440 "	" 2.5738 "	= 46.60 "
1.2221 "	" 2.1811 "	= 46.66 "
1.2871 "	" 2.2999 "	= 46.74 "
Mean = 46.66.		

The theoretical percentage of Mo in Na_2MoO_4 is 46.60 if Mo = 96, this being the number given by the most recent determinations.

The process seems therefore to give very good quantitative results, and is both easy and expeditious. The precipitated molybdate separates easily from the filter and can be heated to low redness without decomposition.

Analogy would seem to offer a good method for tungstic acid, and experimental analyses were made for this purpose, but after repeated trials the process was finally abandoned, as the precipitate came down so finely divided that it passed through the filter. The precipitation seems, however, to be complete, and I have hopes that with closer filter paper greater success will be obtained.

Attempts were made to determine arsenic as arsenate of lead, but without good quantitative results. On the other hand, I tried to determine lead as molybdate, tungstate, and arsenate, but without success, as the presence of an excess of the precipitant in such cases seems to exert an injurious effect, the filtrate or washings speedily becoming cloudy.

It may not be out of place to mention some work upon molybdenum undertaken some time ago, which, though unsuccessful, is not without interest. Various methods were devised of weighing the molybdenum as sulphide.

One way was to precipitate molybdic acid as mercurous molybdate in the usual manner. The suspended molybdate was boiled and sulphydric acid passed into the boiling liquid.

The mercurous molybdate was decomposed and mercurous sulphide and molybdic sulphide were the results. The sulphides were thrown upon a filter and washed with cold sulphydric acid water, dried and ignited in a current of sulphydric acid, but this process failed to give satisfactory results.

Again, sodic molybdic was heated with four parts of dry sodic hyposulphite till all the free sulphur was driven off, leaving, according to theory, $\text{Na}_2\text{SO}_4 + \text{MoS}_3$. The mass was then digested with hot water, filtered and treated as before. When any of the sulphur was left, it was found that some of the molybdenum went into solution as sulphomolybdate of sodium. Even after adopting every precaution, enough was still dissolved to vitiate the analysis:—*American Journal of Science.*

ON THREE MASSES OF METEORIC IRON FROM AUGUSTA CO., VIRGINIA.*

By J. W. MALLET,

Professor of Analytical and Applied Chemistry, University of Virginia.

NEARLY two years ago I learned that a lump of iron, which from the description given of it I supposed to be meteoric, had been turned up by the plough in Augusta Co. in this State, and soon afterwards I obtained possession of this specimen by the kind assistance of Hon. J. B. Baldwin, of Staunton. It proved to be beyond question a meteorite, weighing about 56 lbs.

A few months later, I saw at the Annual Fair of the State Agricultural Society in Richmond, a second mass, of smaller size, weighing about 36 lbs., which had come from the same county, and was exhibited along with some iron ores by Major J. Hotchkiss, of Staunton. Learning from me that I was about to examine and analyse my own specimen, and was anxious to compare it with the other found in the same part of the country, Major Hotchkiss was obliging enough to lend me the latter, and to permit me to cut off enough for analysis.

Quite recently he has placed in my hands a third specimen—also from Augusta Co.—weighing but about 3½ lbs.

I shall speak of these three masses as No. 1, No. 2, and No. 3, in the order in which they are mentioned above; No. 1 being my own specimen, and Nos. 2 and 3 those of Major Hotchkiss.

All three present quite the same general appearance. They are of a very irregular pear shape, one end of each mass being larger and more rounded than the other—the smaller end of each is somewhat flattened, but by concave surfaces, in one direction. No 1 was more massive and rounded than the others—No. 2 most flattened—the latter had some rude resemblance in shape to a shoulder of mutton. The dimensions of the masses before cutting were as follows:—

	No. 1. Centimetres.	No. 2. C.m.	No. 3. C.m.
Maximum length	28	27	11
„ width, at large end ..	21	10	9
„ „ at small end ..	17	19	5
„ thickness, at large end	13	13	8
„ „ at small end	11	5	3

The exact weights before cutting were:—

No. 1.	No. 2.	No. 3.
25,429 grms.	16,441 grms.	1644 grms.

the masses being entire, nothing having been previously detached from any one of them.

The surface of each of the masses is rough and irregular. At some points, which have been rubbed, the iron exhibits its metallic lustre, and traces of its crystalline character may be observed, but nearly the whole surface is covered with a dark brown crust, consisting essentially of hydrated ferric oxide, which varies from about an eighth to a third of an inch in thickness. This crust is hard, and pretty firmly adherent. On exposure to moist air a rusty liquid exudes in drops from numerous points upon the surface, and in this watery liquid chlorine, iron (chiefly as ferrous chloride), and nickel were detected. The masses are of course magnetic, and on examination give evidence of feeble magnetic polarity, with multiple poles.

The union of hardness and toughness in the iron makes it quite difficult to cut, and in attempting to obtain with the planing machine a slice of considerable size the ordinary cutting tools were blunted and broken; it was found necessary to drill a row of holes and connect these by a cut made with the planer.

The specific gravity was taken for Nos. 1 and 2 with solid pieces of about 140 grms. and 95 grms. respectively, cut from the interior of the masses, and for No. 3 with about ten grms. of clean shavings (from the planer) in a specific gravity bottle.

The results were:—

	No. 1.	No. 2.	No. 3.
Specific gravity, at 15° C.	7·853	7·855	7·839

The interior structure of the iron is compact and highly crystalline, of much the same general character throughout, but a few small grains and streaks of a brownish yellow mineral were noticed, which on being picked out and examined proved to be troilite. They are, however, minute fissures running through several portions of the metal.

Traces of the Widmannstättian figures may be detected upon a polished surface even without the aid of an acid, and when the iron has been etched by nitric acid the markings are exceedingly distinct and beautiful, fully as much so as in any specimen of meteoric iron I have ever seen. The general appearance is a good deal like that of the iron from Lenarto in Hungary, and some of the Mexican specimens. In the mass No. 1, upon the principal cut surface, narrow, well-defined bands of alternate nickel-iron and Schreibersite are parallel or intersect each other at angles of about 60° and 120°; in the figures on the principal surface of No. 2, the angles of intersection more nearly approach 90°; on the much smaller cut surface of No. 3, the figures are somewhat more irregular, but the angles approach 60°. By etching surfaces obtained in other planes it was rendered evident that the difference of appearance is merely due to looking at different projections of the same crystalline structure.

The metal soon rusts upon cut surfaces, especially where the exudation of chlorine occurs, and this renders more distinctly visible the slight fissures which penetrate the interior.

The iron is not passive, though very easily rendered so by nitric acid. It reduces copper rather slowly from the sulphate, and if the whole surface be covered by the latter metal and then washed under a stream of water, rubbing hard with the hand or a cloth, a part of the copper comes off very easily, leaving the remainder firmly attached and reproducing very beautifully the Widmannstättian figures, obviously a case of galvanic deposition, the Schreibersite being the electro-negative solid and receiving the coating of copper.

By the prolonged action of acid delicate white laminae of Schreibersite are brought into view, which if com-

* From the *American Journal of Science and Arts*, vol. ii., July, 1871.

pletely detached are found to be flexible and strongly magnetic.

The following are the results of chemical analysis:—

	No. 1.	No. 2.	No. 3.
Iron	88.706	88.365	89.007
Nickel	10.163	10.242	9.964
Cobalt	0.396	0.428	0.387
Copper	0.003	0.004	0.003
Tin	0.002	0.002	0.003
Manganese	trace	—	trace
Phosphorus	0.341	0.362	0.375
Sulphur	0.019	0.008	0.026
Chlorine	0.003	0.002	0.004
Carbon	0.172	0.185	0.122
Silica	0.067	0.061	0.056

99.872 99.659 99.947

These numbers are so closely accordant that there can be no doubt of the masses being essentially identical in chemical composition.

The nickel and iron were separated, in a cold and quite dilute solution, by means of carbonate of baryta, and the precipitates obtained were carefully tested as to purity before the weights were finally accepted as correct.

Considerable quantities of material were used for the determination of the minor constituents. Particular attention was given to the identification of the minute quantity of tin present, as Professor J. Lawrence Smith has lately mentioned* the fact, that he has never found this metal in the course of numerous analyses of meteoric iron. The precipitate with sulphuretted hydrogen, which contained the tin and copper, was in each case obtained from a solution of more than a hundred grms. of the iron.

I feel satisfied that the chlorine is not of meteoric origin—not an essential constituent of the original masses—but has been derived from the soil in which the iron has lain imbedded. The exudation of watery drops containing metallic chlorides is observable only at points on the outside and on cut surfaces along the lines of fissures communicating with the outside. Although chlorine is mentioned above as found in the general analyses of the planing machine shavings, I failed altogether to detect it in a specially selected solid piece of some 50 grms. taken from a part of No. 1 destitute of fissures or flaws.

The siliceous residue is set down as silicic acid, but some of it seems to have in reality existed as silicide of iron. A part of this residue having been examined with the blowpipe to identify it as silicic acid, another portion was looked at with a magnifying power of 250 to 500 diameters, and in polarised light was seen to consist of an amorphous powder, and rounded, transparent grains of very small dimensions, for the most part from 0.0025 to 0.0100 millimetre in diameter, of well-marked doubly refracting character.

It seems in the highest degree probable that these three masses of meteoric iron represent portions of a single fall from the heavens, agreeing so closely as they do in external character and appearance, in density and internal structure, and in chemical constitution; having, moreover, all been found at but short distances from each other. The precise localities from which they came are as follows:—

No 1, from a spot on the land of Mr. Robert Van Lear, about five miles (a little east of) north from Staunton, in 38° 14' N. lat. and 79° 10' W. long.

No. 2, from the land of Mr. M. Fackler, about one mile to the south-east of the locality of No. 1.

No 3, about half a mile still further south-east, or rather a little north of a N.W. and S.E. line passing through the last-named locality.

It will be interesting to watch for the possible detection of other masses in the same neighbourhood.

* *Am. Jour. Sci.*, II., xlix., 333, (May, 1870).

This makes the fourth recorded instance of meteorites found within the State of Virginia, the three preceding having been:—

1. Meteoric stone, which fell in Chesterfield Co., June 4th, 1828, (*Am. Journ. Sci.*, I., xv., 195, and xvii., 191).

2. Meteoric iron, found in Grayson Co., described by Professor Rogers of this University in 1852, (*Am. Journ. Sci.*, I., xliii., 169).

3. Meteoric iron, found in Roanoke Co., and described by Professor Rogers in 1842 (*Am. Journ. Sci.*, I., xliii., 169).

ON THE

CHANGE OF COLOUR PRODUCED IN CERTAIN CHEMICAL COMPOUNDS BY HEAT.*

By Professor EDWIN J. HOUSTON,
Of the Central High-School of Philadelphia.

At a meeting of the Optical Section of the Franklin Institute, held April 26th, 1871, Dr. Wm. H. Wahl exhibited specimens of the double iodides of mercury with copper and silver, discovered by Meusel.† The colour of each of these salts is changed in a remarkable manner by the action of obscure heat rays. The author, in connection with Mr. Elihu Thomson, of the Central High School, was led to undertake an extended series of experiments, with a view of ascertaining the law by which these peculiar changes are governed. The author desires to state that Mr. Thomson's share of the investigations was equal to his own.

Familial changes of a similar though less striking nature at once suggested themselves, among the most prominent of which might be mentioned the darkening of the red protoxide of mercury in the preparation of oxygen.

The experiments were conducted as follows:—

The substances were placed in the state of dry powders on strips of sheet copper, and heated by means of an ordinary Bunsen burner.

It soon became evident that quite a number of compounds underwent a change of colour when so exposed. The colours observed, however, together with those already known, appeared at first to present facts of the most discordant nature.

In some cases the colours were changed so as to approach the violet end of the spectrum, while in others they approached the red end. To avoid all sources of error, the conditions of the original experiment were carefully considered. Briefly they are as follows:—

1. A certain colour presented by the compound at ordinary temperatures.

2. A decided change of colour, on the application of obscure heat rays.

3. A complete return of the original colour on the removal of the heat, and the cooling of the body to its former temperature.

Bodies not presenting all these phenomena were rejected.

The largest class of bodies that was excluded by this method was that in which a permanent change of colour was produced by heat. In this case the change is caused either by the heat being raised to a temperature sufficient to cause a decomposition of the body, by a change from the amorphous to the crystalline state, by a partial sublimation and subsequent deposition of the sublimate, by a change in the crystalline form, or by some other permanent change in the arrangement of the molecules.

Changes in colour produced by dehydration were also rejected, as, for instance, in the case of the chloride of

* From advance-sheets of the *Journal of the Franklin Institute*. Communicated by Dr. W. H. Wahl.

† *Ber. d. Deutsch. Chem. Gessell.*, iii., 123. *Jr. für Prakt. Chem.*, II., ii., 136.

cobalt, which, when hydrated, is a pale pink, but when anhydrous, a deep blue. Hydrated and anhydrous salts are distinct chemical compounds, and have therefore a different molecular arrangement. A class of cases of a somewhat similar nature was also rejected. Here the change of colour was produced by a loss of the water of crystallisation, as, for instance, the sulphate of copper, which changes from a deep blue to a white.

After these sources of error were removed and quite a number of bodies discovered presenting phenomena fulfilling all the requirements of the original experiment, the law became evident. *In every case the colour in its change approached the red or heat end of the spectrum.* Not a single exception to this law was observed.

Before stating the explanation of the way in which these changes are produced, a few words in reference to the relation existing between light and heat may be necessary. That light and heat are produced by a vibratory motion of the molecules of bodies, and that they differ from each other, merely in the rapidity of the vibrations of these molecules, the facts presented by the science of the present day, leaves scarcely room for doubt. A hot body differs from another cooler than itself, not in virtue of any peculiar substance or fluid which it possesses, but simply in the fact that its molecules are in more rapid motion. Increasing the temperature of a body is equivalent to increasing the rapidity of the vibration of its molecules. As the body is made hotter, its molecules vibrate more and more rapidly, until finally a red heat is obtained, and light is emitted along with the heat. Now we know that a ray of white light, popularly speaking, is a mixture of seven different kinds of rays, viz., the colours of the solar spectrum. Moreover, we know by actual measurement, that these colours, in the order of the number of vibrations required to produce them, commencing with the least, are as follows: red, orange, yellow, green, blue, indigo, and violet, those of the violet being about twice as rapid as those of the red.

If, then, light differs from heat, merely in the fact that the molecules of a body emitting light are in more rapid motion than those of a body emitting heat, when that rapidity in the vibrations of the molecules of a hot body is reached, that it commences to give out light along with the heat, the colour first emitted should be red, since that colour is produced by the least number of vibrations per second, and the colours which successively appear should be orange, yellow, green, blue, indigo, and violet, until finally, these by their intermixture produce white light, and the body becomes *white-hot*. These considerations are fully sustained by the beautiful experiment of Draper, who viewed through a prism the light emitted by a platinum wire heated by a current of dynamical electricity. The colour which first appeared was red, and then successively, orange, yellow, green, blue, indigo, and violet, or more accurately, when the platinum wire became white-hot, it gave a continuous spectrum from the red to the violet.

The boundary between heat and light, then, is found at the extreme end of the red of the spectrum. It is evident that though the range of the spectrum must vary with the sensibility of the eye of the observer—that is, that the heat vibrations will become light vibrations sooner to some eyes than to others—yet in all cases the colour first observed will not be a pure red, but a dark brown; a colour produced by the mixture of black, or the absence of colour with the few red rays first emitted.

It should be borne in mind that the arrangement of the spectrum into seven colours is merely a matter of convenience. In point of fact there is an almost infinite variety of tints. The red, for instance, is merely taken at the mean of the dark red and the orange-reds, and so for the other colours.

Remembering these preliminary considerations a fuller statement of the law of the changes may now be given.

In all cases in which the colour of a body is changed

by the application of heat, and the original colour regained on cooling, the nature of the body being in no wise altered, the character of the change is as follows: the addition of heat causes the colour to pass from one of a greater to one of a less number of vibrations; the obstruction of heat from one of less to one of a greater number.

In accordance with this law, violets are changed by heat into indigo violets or indigoes, indigoes into blues, blues into bluish-greens or indigoes, greens into yellowish-greens or yellows, yellows into orange-yellows or oranges, oranges into orange-reds or reds, and finally reds into brownish-reds or blacks; by cold the inverse order is observed. In many instances substances were noticed that ran down the scale two or more colours; for example, the green iodide of mercury, which passes from yellowish-green through the yellow, and orange to the red.

Among the most sensitive substances noticed are the following, arranged by their colours in the order of the spectrum.

REDS.—*Ferrocyanide of Copper.*—Colour at ordinary temperature, mahogany-brown; darkens by heat to brownish-black, original colour returning slowly on cooling.

Brown-Red Sulphide of Antimony—*Kermes mineral.*—Colour brownish-red; changes to darker brownish-red.

Anhydrous Sesquioxide of Iron.—Colour, brownish-red; changes to dark red, brown, brownish-black and black at a temperature greatly below a red heat.

Subiodide of Copper.—Colour, dark red. The changes presented by this substance are very remarkable. On the application of quite a low heat it changes to darker red, and afterwards to a brownish-red, brown, brownish-black, and finally almost a black. The return to its original colour on cooling is rapid.

Protosulphide of Mercury—*Vermillion.*—Colour, bright red, or vermilion; darkens to brownish-red.

Subchromate of Lead.—Colour, red; changes quite readily to dark red and brownish-red.

Red Oxide of Lead—*Red Lead.*—Colour, red; changes readily to dark red.

Bichromate of Potassa.—Colour, red; changes to dark red. The change in this case is best observed by heating a small crystal of the salt.

ORANGES.—*Bisulphide of Arsenic*—*Realgar.*—Colour, when pulverised, orange-red; changes to red, dark red, and brown; returns readily.

Protoxide of Mercury—*Red Precipitate.*—Colour, orange-red; changes to red, dark red, and brownish-red.

Iodide of Lead.—Colour, orange; changes to darker orange, orange-red, and red.

Oxalate of the Protoxide of Iron.—Colour, light orange; darkens. In this case the heat must be quite low, as the substance is readily decomposed.

YELLOWS.—*Chromate of Lead.*—Colour, yellowish orange; changes to orange, orange-red, and deep orange-red.

Subsulphate of Mercury—*Turpith Mineral.*—Colour, yellow; changes to orange-yellow, orange, and orange-red.

Chromate of Baryta.—Colour, yellow; changes to orange-yellow.

Bisulphide of Tin—*Mosaic Gold.*—Colour, brownish orange-yellow; changes to a dark red very nearly approaching a black; quite sensitive.

Tersulphide of Arsenic—*Yellow Orpiment.*—Colour, orange-yellow; changes to deep orange-yellow, yellow, orange-red, and red.

GREENS.—*Subiodide of Silver.*—Colour, greenish-yellow; very sensitive; changes first to an orange-yellow, and then to a deep orange.

Subiodide of Mercury—*Green Iodide.*—Colour, yellowish-green; more sensitive than the preceding; changes to a yellowish-green, and then successively to an orange-green, reddish-orange, red, and brownish-red. These changes succeed each other very rapidly. They may be best observed by heating at once up to the brownish-red,

and noting the changes of colour that occur as the body cools.

In all the above cases the original colour is fully regained on cooling.

The substances named are by no means all that have been observed to come under the law. Quite a number of other compounds have been noticed; but none of them are as sensitive as those already mentioned. In no case, however, has any compound been found of the colour of blue, indigo, or violet, that, in the solid state, undergoes any decided change whatever, on the application of a temperature short of that producing either a decomposition or a permanent change in the arrangement of its molecules. Nor is this fact contrary to what might be expected. Near the heat end of the spectrum, where the difference between the light and heat vibrations is not so great, we might reasonably expect the particles of a solid to be influenced by each, and to accept a motion which should be a mean of the two, but when we get as far in the spectrum as the blue or indigo, the greatest heat that we can intermingle with the blue or indigo, even if pushed to the point of incandescence, would be but dull red. Now long before this temperature is reached most bodies would undergo decomposition, and were this not the case, even then we could hardly expect the particles of a solid, trammelled as they are in their freedom of motion by the force of cohesion, to accept a mean of two kinds of vibrations, which differ so greatly in their wave lengths. Still it must be borne in mind that solids differ very greatly from each other in the freedom of motion of their molecules, and it is not improbable that a number of solids as high in the scale of colour as the blues, indigos, or violets, may eventually be found conforming to the law.

A few very significant facts were noticed in this connection in the case of two pure white substances, viz., the oxides of zinc and of tin; their behaviour is as follows:—

Oxide of Zinc.—*Nihil Album*.—Colour, white; changes on the application of heat to a scarcely perceptible bluish-white, green, and yellowish-green. Does not entirely return on cooling, though it resumes nearly its original colour.

Oxide of Tin.—Colour, white; here the range is more remarkable. It changes first to a pale green, then to a decided yellowish-green, and even runs as far down the scale as orange and reddish-orange; returns on cooling to a greenish-white.

These two substances have not been included in the regular list of solids, as they fall somewhat short of the conditions of the original experiment. They conform sufficiently to it, however, to call attention to their behaviour.

Experiments were also made on solutions of various solids. As a general rule, it has been found that a substance in solution is more sensitive to the action of heat than when in the solid state. This, indeed, should be so, as the action of the solvent is simply, by its adhesion for the solid, to separate it into very small particles and to give them much greater freedom of motion. Solids in solution have been found as high in the scale as the violet, which conform perfectly to the law.

These experiments were conducted as follows:—

The solution was made of the required strength and then divided between two thin glass test-tubes, of the same size and thickness. They were then held, side by side, between the eye and the light, and carefully compared by transmitted light. If any difference in tint was observed, the solutions were poured together and again thoroughly mixed. If any difference still existed on again dividing them between the two test-tubes, one of the tubes was rejected as differing in thickness or colour from the other, and replaced by another until exactly the same tint was obtained. It will readily be seen that these precautions were necessary, in order that the results obtained should not be equivocal. One of the solutions was heated

in a Bunsen burner, and the change carefully noted by comparison from time to time. Of course the highest temperature was limited to the boiling-point of the solution under the pressure of the atmosphere. In many cases, however, decided changes were observed long before even this point was reached. No experiments were tried on temperatures obtained by boiling under high pressures in confined glass vessels, though there is every reason to believe that by these means splendid results would be obtained. It is proposed, if time allows, to pursue the investigation in this direction at some future day.

Of course, in all cases where the colour did not entirely re-appear on cooling, the experiment was rejected.

The solvent used was water. As the colour of a solid in solution varies with the strength of the solution, it will be understood that in all cases the amount of solid dissolved was that requisite to produce the tint described.

The following are amongst the most sensitive substances noticed:—

REDS.—*Rose Aniline*.—Solution of a strength sufficient to produce a decided red; darkens perceptibly on the application of a boiling heat.

Decoction of Logwood.—Solution of a deep red; darkens on the application of heat.

Chloride of Cobalt.—Colour of solution, pinkish-red; changes to a darker pinkish-red.

Sesquisulphate of Iron.—Colour of solution, light red; changes to brownish-red.

ORANGES.—*Chronic Acid*.—Colour of solution, reddish-orange; changes to an orange mixed with a greater amount of red.

Bichromate of Ammonia.—Colour of solution, orange-red; changes to a pure red.

Sesquichloride of Iron.—Colour of a weak solution, orange-red; very sensitive; changes to red and brownish-red.

Bichromate of Potassa.—Solution of an orange-red; changes to a red.

YELLOWS.—*Sesquinitrate of Iron*.—Colour of solution, brownish-yellow; changes to brownish-red.

GREENS.—*Ferrocyanide of Potassium*.—Solution of a yellowish-green; changes to a yellow.

Chromate of Potassa.—Solution of a yellowish-green; changes to a yellow.

Nitrate of Nickel.—Solution, pale green; changes to pale yellowish-green.

Sulphate of Nickel.—Solution, green; changes to yellowish-green.

BLUES.—*Chloride of Copper*.—Colour of weak solution, bluish-green; changes to a very decided yellowish-green. This substance is quite sensitive, the colour returning rapidly on cooling.

Sulphate of Copper.—Solution of a decided blue; changes to a very decided green at the boiling-point of the solution. Returns to its original colour rapidly on removal from the heat.

VIOLETS.—*Ammonio-Oxide of Nickel*.—Solution of a violet-blue; changes to a light blue; returns tully on cooling, and cannot therefore be attributed to any loss of ammonia.

Solution of Litmus.—Colour, violet; changes to an indigo-blue.

It may be objected that the substances noticed do not present as great a range of changes as those observed in solids. It must be remembered, however, that the temperature in no case differed much from the ordinary temperature, being never much greater than 220° F., while in the experiments with solids the temperature was often more than three times as great. We feel sure that experiments with liquids at higher boiling-points will show substances running down the scale much further than the observed solids.

The Action of Cold.—It would appear from the law already stated, that the colour of a body is affected by its temperature, and that in proportion as this temperature is

raised, the colour is lowered; moreover, considering the colour emitted by the body at its higher temperature, the colour is always raised in the spectrum as the body cools. For example, take the case of the green iodide of mercury, which, as before mentioned, is yellowish-green at ordinary temperatures. By the action of heat, its colour is successively lowered through the yellow, orange, and red, which latter is reached at the maximum temperature of exposure. Cool the body from this point, and its colour will become orange, yellow, and yellowish-green, respectively.

Now, the same reasoning that applies to the cooling of the body from this higher temperature should also apply, though not with equal force, to its cooling from any temperature, such, for instance, as that of the place in which the body is situated. The colour emitted by a body at any temperature is always lower than it would be were it not for the intermingling of the heat vibrations. Remove it as much as possible from the influence of these vibrations, or, in other words, cool it, and the emitted light must be of a higher pitch of colour. It would appear then, that as the effect of raising the temperature of a body above its ordinary temperature is to lower the pitch of the emitted light, so cooling it below that temperature must be to raise the pitch. The raising, however, would hardly be as great, proportionally, as the lowering. As we recede from the boundary of the heat and light vibrations, we lessen the chance of their producing by intermingling a resulting mean vibration.

With a view of testing the truth of these theoretical considerations, experiments on the action of cold on substances in both the solid and liquid condition were made.

(To be continued).

CORRESPONDENCE.

THE AMMONIA PROCESS.

To the Editor of the Chemical News.

SIR,—In your issue of 7th July, there appeared a letter from Mr. Wanklyn on the success of his ammonia process; he concludes by saying that the sanitary officers of the Indian Government have adopted it. This is correct, but I am sorry to say that they adopted it rather too hastily, and that the results of the process, as far as has been published, say little in its favour. I have had occasion to examine the methods laid down for the analysis of water in India, both by personal experiment and by examination of the published results of the analyses made in Bengal, and as regards the ammonia-process, the results are most unsatisfactory: in the hands of other analysts it has given the wildest quantities imaginable; in my own it has been a complete failure.

Finding that water after water gave no albumenoid ammonia when treated according to Messrs. Wanklyn and Chapman's instructions, I made some test-experiments with water containing natural organic matter, quinine wine, and ammonia. I found that neither carbonate of soda nor the alkaline solution of permanganate evolved any ammonia from a quantity of fresh urine which should have given 2 milligrammes; urine not perfectly fresh would give 0.01 to 0.02 milligramme of ammonia. If before or after the experiment I added ammonia (as sulphate) to the half-litre of water in the retort I could always obtain it; even from 0.05 milligramme I would obtain 0.02 to 0.04 in the distillate.

The alkaline solution of permanganate failed to evolve any ammonia from water to which quinine had been added, or from water containing enough natural vegetable matter to decolourise a standard solution of permanganate nearly as fast as it could be poured in (no nitrites or ferrous salts being present).

Neither do Indian waters, as far as my experience

goes, contain anything like the amount of ammonia said to be contained in English waters. I have never yet succeeded in detecting it, except in waters obviously containing sewage in considerable quantity; and when distilling water for laboratory use, I fail to detect ammonia in the first 100 c.c. distilled over from ten litres of ordinary well-water. I may add that my Nessler's solution is not in fault, as I can detect 0.01 milligrammes of ammonia in a distillate.

EDWARD NICHOLSON, Asst. Surg. R.A.,
Analyst of Waters, Mysore and Ceder Districts.

Bangalore,
Aug. 18, 1871.

MISCELLANEOUS.

New Appointment.—We are glad to find that Mr. Robert Routledge, who took the first place in honours for chemistry at the final B.Sc. examination of the London University last year, and who at a previous examination took first-class honours in Natural Philosophy, has been appointed conductor of the classes in Chemistry and Physical Science at the Manchester Mechanics' Institution. These classes, which are held in the evening, consist of courses on Applied Mechanics, Steam and the Steam Engine, Acoustics, Light and Heat, Magnetism and Electricity, Inorganic and Practical Chemistry.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 11, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Researches on the Origin of the Heat set free when the Motion Imparted to a Disc of Copper is Stopped by the Action of an Electro-Magnet.—P. A. Favre.

Constitution of Luminous Spectra.—Lecoq de Boisbaudran.

Combination of Alcohol with Bases.—Dr. Berthelot.—This lengthy and very valuable memoir is divided into the following sections:—Introduction; alcohols properly so called, viz., ordinary alcohol, C_2H_5O ; glycerine, $C_3H_7O_3$; mannite, $C_{12}H_{24}O_{12}$; gumphenols, viz., ordinary phenol, $C_{12}H_{10}O_2$; phenates of soda, potassa, ammonia, lime, and baryta; trimethylated phenol (picric acid)— $C_{12}H_3(NO_2)_3O_2$.

aldehydes; acids of mixed functions (*acides à fonction mixte*); salicylic acid; lactic acid, $C_4H_6O_3$; tartaric acid, $C_4H_4O_6$.

Can the Leaves of Plants Absorb Liquid Water?—L. Cailletet. —A very important phyto-physiological memoir.

As usual, this number contains important astronomical, geological, and meteorological papers.

September 18, 1871.

This number opens with the second portion of an important and exhaustive monograph:—

Rocks met with by Perforating the Western Alps between Modane and Bardonnèche.—Elié de Beaumont.—To this paper are added several interesting notes elucidating the origin of the idea of constructing this gigantic work, which was first broached, some thirty years ago, by M. Medail, of Bardonnèche, in a pamphlet published at Lyons.

Thermal Researches on Mixtures.—P. A. Favre.—The continuation of a monograph, portions of which have been published in *Comptes Rendus*, vols. I., II., lix., lxi., the present being vol. lxxiii. This portion contains a series of tabulated forms exhibiting results of experiments.

Spectra of the Substances belonging to the Nitrogen and Chlorine Class of Elements.—A. Ditte.

Spectra of Selenium and Tellurium.—G. Salet.—The contents of these papers are not suited for useful abstraction.

Thermo-Chemical Researches on Ammoniacal Salts.—Dr. Berthelot.—Since the value of this essay depends chiefly on a series of lengthy formulæ, it is not possible to enter into any details.

Spontaneous Decomposition of Bisulphite of Potassa.—C. Saint-Pierre.—The author relates at length the results of some observations made on solutions of the salt alluded to, kept in closed vessels for several years. From these observations it appears that a solution of bisulphite of potassa becomes spontaneously decomposed, yielding sulphur, sulphuric and thionic acids. The author is engaged with similar experiments on other bisulphites.

On Methyl-Diphenylamine.—C. Bardy.—This paper is entirely written with the view to prove that the discovery of the substance just named, by the reaction of methyl-aniline upon chlorhydrate of aniline, described by C. Girard and G. Vogt (see CHEMICAL NEWS, vol. xxiv., p. 167), had been described some time ago (January, 1870), and published by the author in the *Moniteur Scientifique*, 1870, p. 553, and in *Brevet d'Invention*, No. 68,713.

September 25, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Thermal Researches on the Electrolysis of the Alkaline Bases and Alkaline Sulphates.—P. A. Favre.—The contents of this valuable and lengthy monograph do not admit of any useful abstraction.

Letter from J. Pierre to M. Demas on the Phenomena Observed by J. Pierre and E. Puchot by the Simultaneous Distillation of Water and of certain Alcohols.—This communication bears upon the subject mentioned in the CHEMICAL NEWS, vol. xxiv., p. 167; but, since the contents of this paper consist mainly of a series of cyphers relating to results obtained, we need not here enter any further into this matter, which will be communicated more fully at a future date by the authors.

Relation Existing between the Spectral Properties Exhibited by the Elements with their Physiological Properties.—F. Papillon.

Researches on the Reciprocal Conversion of the Allotropic States of Phosphorus.—(First part).—G. Lemoine.—This monograph, elucidated by a series of tabulated forms containing figures relating to results of experiments, contains the record of a most important scientific discovery, and proves, practically, that exact scientific research is reviving rapidly in France. The *resumé* of the labours of this *savant* on the subject in question will be published with the second portion of this paper.

Note on the French and Foreign Malt Liquors Consumed in Paris.—E. Monier.—This paper contains the results of the analysis of twelve different samples of beer, six of which are brewed in France, the rest in other European countries. The sp. gr. of these samples varies from 1.003 to 1.023. The quantity of alcohol, by bulk (c.c. in 1000 grms.), varies from 32.5 (a French brewed beer) to 60.5 (Burton pale ale); glucose, from 4.8 (French beer) to 16.30 (so-called Strasburg beer, but brewed at Paris) grms.; dextrine, albuminoid substances, &c., from 3.70 (French beer) to 58.40 (Munich, Bavarian beer) grms.; salts, from 1.60 (French beer) to 2.80 (Burton pale ale) grms.

New Zinc Paint.—M. Artus.—The author, connected with the Vieille-Montagne Co., exhibits at the meeting of the Academy samples of zinc-white made up with silicate of potassa, and used to paint zinc and other objects. This paint, which resembles stone in aspect, is air-, sun-, and water-proof, and is especially applicable to zinc-covered roofs, but also to plaster, cement, bricks, and other objects. It is also useful for rendering wood, paper, and other readily-inflammable tissues, such as are used, for instance, in theatrical decorations, unflammable.

Polytechnisches Journal von Dingler, second number for August, 1871.

The following original papers bearing upon chemistry and collateral subjects are published in this number:—

Modified Arrangement of Leclanché's Manganese Galvanic Cell.—M. Beaumans.—The description, accompanied by a woodcut, of an important improvement upon the Leclanché galvanic element; it would, however, require the reproduction of the woodcut to make the subject understood.

Studies on the Blast Furnaces Used for the Production of Iron.—C. Schiæz.—This portion of the continuation of this exhaustive monograph contains the following sections:—Transmission of heat through the walls of the furnaces; reducibility of the ores; direct and indirect reduction; modulus of charge; causes which accelerate or retard the reduction and carburization of the iron reduction and carburization of the iron.

Question of the Dinæa Brick-Making in general.—Dr. C. Bischof.—This paper treats on the conditions to be observed in the making of a peculiar kind of fire-brick, the properties of which are very similar to what in this country is known as Flintshire stone.

Recovering the Nitrous Acid in the Process of Sulphuric Acid Manufacture.—Dr. G. Lunge.—A lengthy essay on this subject, illustrated by several engravings.

Preparation of an Oxidised Aniline-Black Paste, and on an Aniline China Ink.—A. Müller.—20 grms. of chlorate of potassa,

40 grms. of sulphate of copper, 16 grms. of sal-ammoniac, 40 grms. of hydrochlorate of aniline, are dissolved in 500 c.c. of water, and the mixture heated upon a water-bath to 60°. After some two or three minutes, the basin or vessel containing the mixture is removed from the water-bath, because it has a tendency to boil over, in consequence of the strong evolution of vapours of trichloro-nitroform. It happens that after some two or three hours the thickish magma has not become quite black, it is again heated to 60°. The pasty mass is next left for two days exposed to open air, after which the mass is washed until all the salts soluble in water are removed, and after having become half dry is removed from the filter. The deep coaly-black-coloured paste is either at once thickened with albumen and kept for use (for calico-printing purposes) in tinned iron canisters, or it is dried over sulphuric acid in vacuum, then exhibiting a soft, not glossy, intensely deep black-coloured powder, which, on a preliminary analysis, gave results leading to the formula $C_{14}H_{14}N_2O_{12}$. When the powder is mixed with some gum-water it is an excellent substitute for Indian ink.

Rapid Method of Drying Glue.—Dr. H. Fleck.—This paper treats on a plan of separating, rather than drying, glue from its aqueous solutions by the aid of salts, and gives to glue-boilers a few hints how to apply this method, which yields a glue which is not transparent but turbid.

Gold-like Alloy.—Dr. E. Dingler.—This alloy consists of:—Copper, 53.86; zinc, 40.22; lead, 1.90. It is both inexpensive and durable as well as malleable.

Production of Bismuth in Saxony.—Dr. Wagner.—It appears that this country produces 32,000 lbs. of the metal annually, and that, since bismuth is as yet nowhere produced in any considerable quantity, Saxony rules the market of this article.

Cheap Mode of Preparing Pure Dextrine.—O. Ficinus.—500 parts of potato-starch are mixed with 1500 parts of cold distilled water and 8 parts of pure oxalic acid, and this mixture placed in a suitable vessel on a water-bath, and heated until a small sample tested with iodine solution does not produce the reaction of starch. When this is found to be the case the vessel is immediately removed from the water-bath, and the liquid neutralised with pure carbonate of lime. After having been left standing for a couple of days the liquor is filtered, and the clear filtrate evaporated upon a water-bath until the mass has become quite a paste, which is removed by a spatula, and, having been made into a thin cake, is placed upon paper and further dried in a warm place; 220 parts of pure dextrine are thus obtained.

Journal de Pharmacie et de Chimie, July, 1871.

This number contains the following original papers and memoirs:—

Experimental Researches on the Preparation and Properties of the Chlorides of Propyl and Butyl.—J. Pierre and M. Puchot.—Propylic chloride, C_3H_7Cl , is prepared either by passing gaseous and dry hydrochloric acid into propylic alcohol until no more of the gas is absorbed, and distillation of the mixture thus obtained, or by causing perchloride of phosphorus to act upon pure propylic alcohol, care being taken to apply to the vessel wherein the liquids are contained a cooling mixture, and a peculiar arrangement of the apparatus so as to carry off, without causing inconvenience to the operators, the hydrochloric acid gas which is set free. With due care, 480 grms. of the propylic alcohol yield 180 grms. of the pure chloride, which is a very limpid, colourless, mobile liquid, exhibiting a pleasant sweetish somewhat alliaceous smell, and boils at 46.5°; sp. gr., at 0° = 0.9156. Butylic chloride, C_4H_9Cl , prepared in the same manner as just described, butylic alcohol being of course substituted for the propylic, is also a very limpid, mobile, colourless liquid, boiling at 69°; sp. gr., at 0° = 0.8953.

On Gelatiniform Matter or Albuminose, on Exalbumine, and on Galactine.—A. Morin.—The introduction to this essay gives a review of the labours of Drs. G. J. Mulder, Prevost, Mialhe, Corvisart, Tiedemann, and Gmelin, and on the nitrogenous substance met with in the animal organisms generally referred to as proteine compounds. The main portion of this paper is devoted to the subject of galactine, which term the author desires to be substituted for the other words above mentioned. Galactine, though chiefly met with in milk, is also a constituent of the animal body. The dry residue of the carefully conducted evaporation of milk consists, in round numbers, of:—Caseine, 10 parts; albumen, 1; galactine, 1; butter, 10; milk-sugar, 20; salts, 1; a nitrogenous matter soluble in alcohol, 2 parts. Galactine in fresh state is a somewhat viscous mass, which becomes solid on drying, but remains soft as putty and may be kneaded by the hand into any shape. Galactine is soluble in water, insoluble in ether and alcohol, is not by long boiling with water converted into gelatine, is precipitated like gelatine by tannin, with this characteristic difference that, whereas the precipitate produced by tannin in gelatine is insoluble at a high temperature, the precipitate produced by tannin in a solution of galactine is dissolved at 60°. Galactine, like caseine, has the property of forming emulsions with fatty substances.

Report on the Preparation of Oxygen for Pharmaceutical Purposes.—Dr. Baudrimont.—This very lengthy yet only preliminary paper, illustrated by woodcuts, treats exhaustively on the preparation of the gas alluded to, so as to make it safe and yield a pure gas. The following are the sections:—Action of the heat upon chlorate of potassa; action of the oxides, viz., of copper, peroxide of iron, and manganese, mixed with the chlorate of potassa; chemical action; mode of preparation of oxygen. The author advises:—That the peroxide of manganese should never be used unless previously calcined, whereby, although its composition be modified, it does not lose its useful effect in assisting the ready decomposition of the chlorate of potassa; to mix the calcined oxide, in the proportion of equal parts by

weight with the chloride of potassa, care being taken to pulverise the last-named substance first; to apply to the vessel containing the mixture as little heat as possible; to test the purity of the chloride of potassa; and to wash the gas through water; while, lastly, care should be taken to make the tubing required of as large internal diameter as consistent with the size of the retort and quantity of material used at one time, it being preferable not to operate upon too large a quantity of the mixture at a time.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, Nos. 217 and 222 inclusive, January to July, 1871.

This collection, published in one cover owing to events to which it is unnecessary further to allude, contains only the following original essay relating to chemistry:—

Processes in Uae at the Dieuze Alkali-Works for the Denaturation and Utilisation of the Residues of Soda and Chlorine Manufacture.—P. Buquet.—This essay, far too lengthy for abstraction, contains the complete account of processes in actual use on the large scale, and so perfect that to the authors, P. Buquet and W. Hofmann, the chemical prize of the society above alluded to was given on July 15, 1870. This essay is divided into the following sections:—Introduction; theory of the question to be solved; oxidation of the char (soda-waste); lixiviation of the char; neutralisation of the acid chloride of manganese; utilisation of the sulphuretted hydrogen; precipitation of the iron; precipitation of the manganese; treatment of the residue; separation of the sulphate and peroxide of manganese from each other; utilisation of the sulphate of manganese for the preparation of nitric acid. An alkali-works, where 20,000 litres of chloride of manganese and 30,000 kilos. of soda-waste are daily obtained, may produce by the process herein briefly alluded to:—Pure sulphur, 1400 kilos.; sulphur as sulphuret, 2200; peroxide of manganese at 60 per cent, 770; hyposulphite of lime, 20; dry sulphate of lime, about 600 kilos.

Revue Universelle des Mines, de la Métallurgie, des Travaux Publics des Sciences et des Arts Appliqués à l'Industrie, May and June, 1871.

The only original paper relating collaterally to chemistry met with in this number is:—

Zinc Metallurgy of the Nouvelle-Montagne Company.—H. Massart.—This memoir, accompanied by a series of engravings, treats very exhaustively on the subject alluded to, entering into all the technical as well as the financial details of the mode of working of this Company, which has its works and mines in Belgium. For all who are interested in zinc metallurgy, this paper contains matter of very great value. The percentage composition of roasted blende is:—ZnO, 53.20; Fe₂O₃, 20.93; CaO, 5.86; PbO, 3.26; SiO₂, 8.15; SO₂, 8.60. Calcined calamine consists, in 100 parts, of:—ZnO, 53.27; Fe₂O₃, 26.42; CaO, 4.63; SiO₂, 16.23. Metallic zinc from blende consists, in 100 parts, of:—Zinc, 98.63; iron, 1.05; lead, 0.25; lime, 0.04. Zinc from calamine contains, in percentages:—Zinc, 99.25; iron, 0.62; lead, 0.13. Refined zinc consists, in 100 parts, of:—Zinc, 99.70; iron, 0.20; lead, 0.10.

Though not strictly belonging to the subjects usually treated of in our pages, we quote the following paper:—

Economic Conditions of the Mines of the Island of Sardinia.—M. Sella.—The copious abstract of an exhaustive report presented to the Committee of Inquiry on this subject, elected by the Chamber of Representatives of the Kingdom of Italy.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, September 14, 1871.

Continuation of the Essay, Studies on the Chemical Dissociation of Bodies.—C. Mène.

Description of Modifications of the Bunsen Gas Burner.—C. Mène.—Illustrated by woodcuts representing various contrivances by which these burners are adapted for different operations.

Analysis of Arable Soil from the Sologne.—F. Masure.—The tabulated results of the estimation of various constituents, nitrogen, phosphoric acid, alkalies, as well as description of the physical and hygroscopic properties of surface-soil and sub-soil of the portion of Central France above-named.

September 21, 1871.

The only original paper in this number is a description, accompanied by woodcuts, of

An Electrical Metronome of the Opera at Paris.—J. Duboscq.—It appears that this instrument, belonging to those used for acoustics, is very ingeniously made and answers the purpose perfectly.

September 28, 1871.

Among the original matter contained in this number we notice:—

Distillation of Beet-Root Molasses.—R. Corenwinder.—The gist of this paper bears upon the utility of the addition of sulphuric acid to the molasses, and upon the quantity of that acid required in any special case, which may be ascertained by a volumetrical assay. The author points out that not only the hases present in the molasses have to be saturated but that an excess of acid, sufficient to prevent during the fermentation the formation of organic acids, is absolutely required, because, by the formation of organic acids, less alcohol is obtained, as well as of an inferior quality, because it is contaminated with ethers which cause the alcohol to be bad to the taste and also injurious.

Tabulated Review of the Composition of Fertilising Substances which may be added to Manures, or are fit for use as such by themselves.—C. Mène.—A very useful catalogue, containing the results of analyses, peremptorily quoted, of such substances as various kinds of wood sawdust, offal from dye-works, glue-boilers, and various substances. This paper is to be continued.

Studies on the Dissociation of Chemical Bodies.—C. Mène.—The continuation of an essay on this subject.

Bibliography.—"M. Georges Ville et ses Engrais Chimiques," par M. Severin Leroy; A. Sagnier, Editeur: Paris, 1871. We call attention to this pamphlet, the contents of which are very well spoken of in this number. Many of our readers will remember that the chemical manures of G. Ville, and his agricultural experiments, have given rise to a great deal of polemic. The French pamphlet here alluded to contains, judging from what is said about it, a thoroughly disinterested review of the whole subject.

NOTES AND QUERIES.

Cement to Resist Sulphuric Acid.—Can any of your readers kindly tell me of a good cement which will resist sulphuric acid and hold glass and lead together.—H. R. YARDLEY.

Crimson Spirit.—This term appears to mean a solution of chloride of tin, and it is likely that, under the name alluded to, the solution you require is sold by dyers, but the name is possibly also given to an ammoniacal solution of cochineal.

Electro-Deposition.—(Reply to "Inquirer.")—You may use a solution of platinum chloride in ether, or you may rub the objects you desire to be platinised with a moistened mixture of platino-chloride of ammonium and cream of tartar. For electro-depositing it appears that the double chloride of platinum and potassium, dissolved in a solution of caustic potassa, is the best fluid; take care to have the iron and copper perfectly bright, well polished, and free also from grease. Aluminium does not appear to have been deposited in the way you mention.

Assaying Iron Pyrites.—Is the ordinary method or methods of assaying iron pyrites for gold defective and faulty? My reason for asking is that it is beginning to be believed that pyrites, such as are worked for sulphuric acid, contain much more gold than is ordinarily admitted, that there is a decided loss in roasting (Crookes and Röhrig's "Metallurgy," Gold and Silver, pp. 629–630, and authorities there cited), and that a method has been devised with which the presence of gold in large amount can be demonstrated. Assays of mine, made upon 8 and 16 oz. lots, showed from 1½ to 40 ozs. gold per ton of 2000 lbs. in pyrites where most other assayers found no gold, and some, in California, ½ oz. The trouble is that no two assays made from pyrites shovelled from the self-same barrel could be made to agree.—J. M. M.

TO CORRESPONDENTS.

* Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give these information respecting scarce numbers and volumes. Vol. xxiv. commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

W. F. Catchside.—There is a letter for this correspondent at our Office.

A. K. & Co.—Fuller's earth is found in Surrey, Kent, Nottinghamshire, and in Scotland. Address to Mr. James Cawley, Nutfield, Surrey.

Carbazotic. (1). Picric acid has been tried as a tonic and antiscorbutic in doses varying from 1–12 to ½ grain, but it is not found to possess any marked medicinal virtues, and its use imparts a yellow tinge to the skin and to the white of the eye. (2). Nitrites when properly prepared are neutral salts; there ought therefore to be no decomposition with the salt you mention. Watts's "Dictionary of Chemistry" will give you further information on the subject.

Dr. E.—There is a paper on the subject in the "Handwörterbuch der reinen und Angewandten Chemie," vol. v., p. 301; consult also Payen, "Précis de Chimie Industrielle," 5th edition, vol. i., p. 432. Both these works are at the Patent Office Library.

J. Young.—The full translation will appear as soon as possible.

C. R. C. Tichborne.—Received with thanks.

J. Galletly.—A proof shall be forwarded.

J. Fyfe.—Bisulphite of ammonia is a solid; you can obtain it from any good operative chemist in London.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

VOL. XXIV. No. 621.

ON ISODINAPHTHYL.

By WATSON SMITH, F.C.S.

INSTEAD of at once dealing with the main subject of this paper, I think a brief view of certain of the results of researches of several eminent chemists, directly bearing on the matter in hand, would be at once interesting and desirable.

The peculiar hydrocarbon diphenyl was first obtained by Fittig* by treating monobrombenzol with sodium :—

Now Berthelot†, in the year 1866, by passing benzol vapour through a porcelain tube heated to bright redness, obtained diphenyl as the chief product of decomposition. Berthelot distinctly says, "the body so obtained is a beautifully crystalline substance, which is identical with Fittig's diphenyl, possessing exactly the melting- and boiling-points given by Fittig, and agreeing generally with that body." A small quantity of chrysene is also said to be formed, and of a solid resinous body, of an orange colour, which is but slightly soluble in alcohol, rendering the same fluorescent. The formula

represents this decomposition.

(1). About the commencement of the year 1867‡, Dr. F. Lossen found that dinaphthyl could be obtained from monobromnaphthalin by the action of sodium, just as Fittig had obtained diphenyl from monobrombenzol—

At the same time he (Lossen) found there was also a small quantity of a polymer formed, which he obtained as a chocolate-brown powder, scarcely at all soluble in alcohol, but more so in ether. It was easily soluble in carbonic disulphide.

(2). Dr. Lossen also found that he could obtain dinaphthyl by the oxidising action, upon naphthalin, of a mixture of manganese peroxide and sulphuric acid—

This mixture he found acted energetically upon naphthalin, there being liberated, with strong effervescence, much carbonic dioxide. When the action was completed, the contents of the retort in which the process was carried on were diluted with water, manganese sulphate and phthalic acid were dissolved out, and unaltered manganese peroxide and a resinous body left behind. The undissolved portion was boiled with absolute alcohol; and the impure body crystallised out from the filtered solution was repeatedly re-crystallised from alcohol. The dinaphthyl was thus obtained in pearly shining scales of a very light yellow colour. Lossen found that it was only possible to obtain the body quite colourless by sublimation.

Thus obtained, dinaphthyl was found to be much more easily soluble in ether than in alcohol, crystallising therefrom in moss-like clusters. By slowly cooling a solution of this body in a mixture of ether and alcohol, it was obtained

crystallised in well-formed regular octahedra. It is very soluble in carbonic disulphide. Benzol dissolves it to much the same extent as alcohol does; and it crystallises from the solution of that body in the same form as it does from alcohol. Dinaphthyl melts at 154° C. Its boiling-point lies above that of mercury. Robert Otto* and Gustav Möries repeated Lossen's experiments with precisely the same results; but they tried, in order to get dinaphthyl formed more easily, and in larger quantity, to form it by first obtaining the mercury compound mercurio-dinaphthyl—

by heating monobromnaphthalin with sodium amalgam (Na_2Hg''), and raising this to a red heat with soda-lime in a porcelain tube. Mercury and a yellow crystalline mass were obtained, the greatest portion of the latter consisting of naphthalin. This yellow mass, on boiling with alcohol, yielded on cooling the rhombic tables of naphthalin abundantly, the mother-liquors exhibiting strong green fluorescence by reflected light and furnishing on evaporation a yellow mass, which, after suitable purification, deposited from alcohol small canary-yellow shining leaf-like crystals, which melted at 133° C. This body was readily soluble in alcohol, ether, and benzol. The solution of the pure hydrocarbon was no longer fluorescent.

They made a combustion, which did not seem to be satisfactory, as they only had 0.066 grm. of substance to work with, and of this they did not feel sure of the perfect purity. The percentage composition they obtained almost exactly corresponded with that of naphthalin. They consider the action to be chiefly

About the close of the year 1866, Berthelot‡ concluded his remarkable series of experiments on the action of certain hydrocarbons upon one another when conducted through a red-hot tube. In one of these experiments he passes the vapour of naphthalin with hydrogen through the tube; and as to the result he says, "Almost no action at all takes place, the naphthalin remaining almost quite unaltered, and only a little benzol and acetylene are obtained."

About nine months ago I undertook, at the suggestion of Mr John Barrow, in the laboratory of whose works I was then engaged, the investigation of the action of heat upon naphthalin, with the object of discovering whether by this means it is possible to obtain anthracene, according to the equation $7(C_{10}H_8) = 5C_{14}H_{10} + 6H$.

This reaction Mr. Barrow supposed might take place on passing the naphthalin vapours through a red-hot tube. I accordingly tried a number of preliminary experiments in this direction, of which the results were as follows :—

(1). The odour and colour of the naphthalin which came through the tube were perceptibly altered; the colour became a deeper brown in proportion as the temperature of the tube was higher. At an incipient white heat a considerable quantity of black smoke came over with the distillate.

(2). A gaseous product was obtained proportionately larger in amount as the temperature employed was higher.

(3). On distilling the brown mass of naphthalin coming through the tube, there was invariably left in the retort a minute quantity whose boiling-point was above 350° C.

I now prepared some pure naphthalin, by treating a quantity of the crude stuff, whilst fused, with warm con-

* Read before the Manchester Literary and Philosophical Society.

§ Ann. d. Ch. und Pharm., Band cxliv., p. 71.

* Ann. d. Ch. und Pharm., 1868, vol. cxlvii., p. 164.

† Zeitschrift f. Ch., 1867, Jan. 31; and Compl. Rend., vol. lxiii., p. 998 and 1077.

centrated sulphuric acid (about 5 per cent by volume); and, after separating, it was again shaken with hot caustic soda solution of sp. gr. = 1.18. The naphthalin thus treated was now purified by fractional distillation, the portion boiling between 210°C . and 212°C . being kept. After another distillation, the perfectly white product obtained was taken for experiment. Into a small flask (a) 152.6 grms. of the pure naphthalin were introduced, and the flask was connected with an iron tube ($\frac{1}{2}$ inch diameter), filled with small fragments of charcoal, to afford a large heated surface. That charcoal had no chemical influence beyond that of affording a large heated surface, was proved by the fact that the same results were obtained when fragments of pumice stone, soda-lime, brick, or the empty tube itself was employed. With the other end of the iron tube was connected a bent glass tube (b) ($\frac{1}{2}$ inch diameter), fitting air-tight into a retort (c) so deep that the end thereof should be below the aperture of the retort-stem. With the extremity of the retort-stem was connected another bent glass tube, dipping into the pneumatic trough, over which was a jar of 340 c.c. capacity, to collect the gaseous products evolved. The iron tube was placed in a "Griffin's gas-furnace," where it was raised to a

The temperatures at which the tube was maintained were not uniform in each experiment; and the volumes of gas evolved was found to vary accordingly. Thus, in the second distillation, the heat was only just perceptibly red, and very little gas was obtained (about 5 c.c. or so).

Quantities of Gas Liberated during each Experiment, the Heat Employed Varying in Intensity.

Distillation.	Intensity of heat of tube.	C.c. of gas evolved.
1st.	Bright red heat.	300
2nd.	Only just red.	Very little, about 5 c.c.
3rd.	Bright red.	460
4th.	Do.	300
5th.	Do.	500
6th.	Do.	403
7th.	Do.	300
8th.	Do.	225
Total		2493

Average temperature = 15°C .

The above measurements of gas evolved were not made with any great accuracy, but are just fair approximations. This gas was tested, and yielded the following results:—

- (1). It gave no milkiness with lime-water.
- (2). It burnt, on ignition, with a lambent bluish flame, tinged at times with a glimmering of the white carbon flame, and, on shaking with lime-water, gave therewith a very slight milkiness; but almost always there was not the slightest glimmer of the carbon flame, and not the slightest cloud

with lime-water after burning.

- (3). The gas, mixed with half its volume of oxygen and inflamed, exploded loudly.

From these evidences we gather that the gas is hydrogen; and the glimmering at times of the carbon flame was probably due to the presence of a little naphthalin vapour mechanically carried over, though certainly a trace of acetylene might be present at times, and would then account for it.

If a calculation be made from the volume of gas evolved, it will be found that this quantity is too great to stand good for the equation

Weight of H actually evolved = 0.2107 grm.
" " required for the above reaction = 0.1861 "

The above is sufficient to show that, as the amount of hydrogen evolved was too great to stand good for the above equation, the body formed from the decomposition (seeing that there was no appreciable separation of carbon) must be richer in carbon and poorer in hydrogen than anthracene is. This point will be again referred to.

Now the crude substance which had been accumulated amounted to 26.3 grms.—that is, 17.23 per cent on the naphthalin used. These 26.3 grms. of crude substance were placed in a small retort with thermometer, and submitted to fractional distillation. A very small quantity of naphthalin came over first, below 220°C .; and then the temperature very rapidly rose to considerably above 360°C ., when most of the body distilled over, leaving a minute quantity of pitch in the retort. In distilling, almost all the substance solidified in the neck of the retort, which had to be kept very hot towards the end of the operation, to get the substance to run down fused into the receiver. At this stage the distilled product closely resembled anthracene in a similar stage of purification, but did not possess the peculiar odour which characterises that body in the crude state, being almost entirely free from odour.

To purify further, the solid hard substance was crushed in a mortar and made into a thin homogeneous paste with light shale spirit (or petroleum spirit), in both of which it

a. Small flask with naphthalin.
b. $\frac{1}{2}$ -inch iron tube, filled with small fragments of charcoal.
c. Retort, to collect distillate.
d. Gas-jar, to collect and measure gas evolved.

bright red heat, in some parts approaching to whiteness. When the iron tube was red-hot, the naphthalin was distilled through cautiously. As soon as it made its appearance in the tube (b), the latter was heated up somewhat strongly, so as not to allow the solidification of the naphthalin. The distillate, when it commenced to run down the bend to the cool part of the tube in the retort, was worked over for a minute or two as briskly as possible; or it would certainly have stopped up that cool part of the tube which dipped below the stopper of the retort, causing a dangerous explosion from the little flask (a).

When the naphthalin began to run fluid into the retort, the distillation was kept up briskly for a time, all solidified particles being speedily re-melted by the hot stream, and carried before it into the retort. All danger of stopping up then ceased, as the whole apparatus was too hot to permit solidification in any part thereof.

The substance distilling over was of a deep brown-red colour, and had acquired a peculiar odour, in addition to that usual in naphthalin. The gaseous product obtained was just sufficient in the first trial to fill the gas-jar (340 c.c.). The distillation was carried on till the flask was just dry, when, on removing the flame of the lamp, there was always a back rush of vapour, accompanied by the dropping back of a dark-looking fluid, amounting in this (the first) distillation to about 1 c.c.

This small quantity of dark-looking substance which had dropped back out of the hot tube, was poured out into a small capsule, and carefully preserved, as the first contribution towards a quantity of the crude substance.

What distilled over into the retort (e), of reddish-brown colour, was now fused, and poured back again into the little distillation-flask (a), from which it was again distilled through the red-hot tube as before, in the first experiment. It not only yielded a little freshly formed substance of high boiling-point, but also left behind a little which had been formed, and carried over amongst the bulk of the naphthalin, in the first distillation. Thus a somewhat larger yield was obtained in the second and subsequent distillations than in the first. These distillations were repeated seven times, to accumulate crude material.

is much less soluble than in benzol. It was then drained on a filter, washed again several times with petroleum or shale spirit, drained, pressed in blotting paper, and dried at a temperature fully sufficient to volatilise the spirit. By this washing it was freed from a small quantity of resinous matter, and from a citron-yellow coloured substance, which coloured the spirit mother-liquors yellow by direct transmitted light, exhibiting a fine blue fluorescence by reflected light.

This fluorescence is similarly acquired when any fluids possessing any solvent action are substituted for the shale spirit.

Finally, the dried substance was sublimed at as low a temperature as possible. The sublimate consisted of a faintly yellowish-white inodorous powder, precisely resembling commercial anthracene sublimed under like conditions, but not possessing the slightest odour. The sublimate may also be obtained in delicate little plates, by very careful and slow sublimation. When possessing the faintest yellow tint, this powder imparts a delicate blue fluorescence to any solvent used.

In another preparation of a further quantity of crude substance, a large iron tube, about 4 or 5 feet long, and about 3½ inches diameter, was used, being placed in a charcoal fire. The heat was almost to whiteness. In this case there was a connection with a pneumatic trough, the open end of the tube dipping into an iron pan acting as receiver. Immense volumes of black smoke were liberated at first;* however, on moderating the heat somewhat, whilst the dense black smoke still poured out, a quantity of undecomposed naphthalin and other matters came over, dropping into the receiver. The black, almost solid mass in the receiver, after being put back into the one-gallon iron still employed, and re-distilled several times, at length left a residue, which, on fractional distillation,

proved to contain some undecomposed naphthalin, this passing over below 220° C. A very appreciable residue however remained, which was distilled over, the temperature rising above 350° C. In this case, however, the solid hard substance obtained had a deep yellow tint, almost inclining to orange; and on triturating in the mortar with benzol (cold), the latter dissolved out a sticky resinous body, which coloured it a fine deep red. After washing once or twice, the crude body remaining was quite freed from this sticky substance, and remained a sulphur-yellow powder. This yellow colour was very much more intense than in the case of the experiments on the minor scale. By re-crystallisation from benzol and sublimation, it was obtained colourless.

A small quantity of this crude orange-yellow body, treated with cold concentrated sulphuric acid, yielded a very fine purple solution, better developed on warming. On heating more strongly, the colour changed to an indigo tint, and then to a dull green. As this reaction is mentioned by C. Liebermann as characteristic of chrysene, I venture to suggest that probably chrysene was present in this yellow crude substance.

With a benzol solution of picric acid in excess, no red compound was formed with this body. It was found to be much more insoluble in alcohol and shale spirit than anthracene is; from these solutions it separates on cooling in larger or smaller rhomboidal plates, according to whether the solutions are more slowly or rapidly cooled. It is almost insoluble in ether, but easily soluble in oil of turpentine, from which it crystallises in beautiful lance-shaped crystals, congregating in clusters. It is, like anthracene, very soluble in carbonic disulphide, even in the cold. The thoroughly purified substance imparts no longer any fluorescence to solvents.

	Carbon tetrachloride.	{ Slightly less soluble than in benzol.	
	Benzol.	{ Sparingly in the cold, pretty freely in the hot fluid.	
Easily soluble.	Carbonic disulphide	{ Easily soluble, even in the cold.	{ Delicate white lance-shaped crystals, in clusters.
	Oil of turpentine.	Very easily soluble.	
Melting-point = 154° C.	Melting-point = 204° C.		
Boiling-point = above 350° C.	Boiling-point = much above 360° C.		

The fusing-point is from 200° to 204° C., and the boiling-point considerably over 360° C., certainly higher than that of anthracene. The subliming-point of this body lies considerably below its boiling-point, like that of anthracene.

A portion of the pure substance was treated with two parts of potassium bichromate and sulphuric acid, when

* Probably caused by the admittance of a small amount of air accidentally.

oxidation took place as energetically as in the case of anthracene under like treatment. No crystals bearing any resemblance to those of anthrachinon could be obtained on treating with benzol. From the product which was obtained, no substance similar to alizarine, nor in fact any colouring matter, could be obtained.

Cold sulphuric acid is without action upon this body; but, when heated, the acid slowly dissolves it, when, if it be quite pure, a very faint purplish-tinted solution is

formed; if not quite pure, but containing a trace of the yellow-coloured body mentioned before, a violet or purple solution is formed, becoming green and then reddish-brown on further warming.

Hot nitric acid oxidises it, with liberation of nitrous fumes, forming heavy oily drops of a nitro-compound of a red colour; on further boiling with a large excess of acid, this compound is slowly dissolved. On addition of water, a light yellow floccular precipitate is thrown down abundantly.

Placed in a glass tube, and chlorine passed over it in the cold, no action takes place; and even on warming to a considerable extent, no change appears to occur. Treated with bromine in the cold, combination takes place with very energetic action.

After many repeated experiments on the subject, I have come to the conclusion that it is impossible to distil pure naphthalene to dryness in any quantity without this body being formed in minute quantity. This may be observed by dipping the thermometer down nearly to the bottom of the retort when the last minute quantity is being vaporised; the thermometer, lowered into this vapour, will be observed speedily to indicate a high temperature, the mercury rapidly rising towards 350°C . If this does not take place on the first distillation,—if the naphthalene, all of which has passed over, be again introduced into the retort, and the same plan again proceeded with, this observation may be made successfully, as a small quantity of high boiling substance carried over in the first distillation will be increased by a further accumulation in the second, and an appreciable quantity will be left behind.

A quantity of the pure substance crystallised from absolute alcohol was taken for analysis. The following results were obtained:—

I. 0.1240 grm. of substance gave 0.4307 grm. CO_2		0.0624 „ H_2O
II. 0.1237 „ „ „ 0.4284 „ CO_2		0.0626 „ H_2O
		Calculated for
	I.	II.
Carbon..	94.72	94.46
Hydrogen ..	5.59	5.62
	100.31	100.08
		100.00
		Calculated for
		C_{10}H_7
		C_{10}H_7
Carbon..	94.72	94.49
Hydrogen ..	5.59	5.51
		100.00

A calculation may also be made from the weight of hydrogen given off in the reaction in the hot tube; and I think it is well worthy of notice, as it was this observation which first led me to think the reaction must be as follows, viz.:—

Weight of naphthalene converted = 26.3 grms. (about).

Volume of hydrogen at 0°C . evolved = 2363 c.c.

Grm. Hydrogen.

Then $\frac{2363}{11200} = 0.2109$ actually obtained.

$2\text{C}_{10}\text{H}_8$ lose H_2 .. 26.3 lose 0.2055 calculated.

Difference 0.0054

For the formula

$7\text{C}_{10}\text{H}_8 = 5\text{C}_{14}\text{H}_{10} + 6\text{H}$, 0.1861 should be liberated.

CONCLUSIONS.

I find from the foregoing facts:—

(1.) That, whereas Berthelot found that diphenyl could be obtained by the action of a high temperature upon benzol, identical with that obtained by Fittig from brombenzol, the analogy does not appear to hold good with dinaphthyl formed from naphthalene.

(2.) That a substance having a higher melting-point, and differing in many respects from Lossen's dinaphthyl, is formed.

(3.) That this body is the chief product of the action of heat upon naphthalene, whether a low temperature, just sufficient to induce decomposition, or a temperature close upon a white heat be employed.

(Finally.) Observing the percentage composition of this body, and the volume of hydrogen approximately found to be evolved in the decomposition, also that the boiling-points of dinaphthyl and this body are by no means very widely different, possibly not far apart, I propose to regard it as an isomer of dinaphthyl, and to name it accordingly isodinaphthyl—

If naphthalene be graphically represented as—

Dr. Lossen's dinaphthyl would appear to be—

α Dinaphthyl.

Melting-point = 154°C .

whilst the isodinaphthyl obtained by myself would stand—

β Dinaphthyl.

Melting-point = 204°C .

Analogously, the α and β naphthols investigated by Wichelhaus, and also by Schaeffer (*Ann. der Chemie und Pharm.*, vol. clii., p. 281), would appear thus:—

α Naphthol.

Melting-point = 94°C .

Boiling-point = 279°C .

Naphthol.

Melting-point = 122°C .

Boiling-point = 287°C .

(OH)

Action of Chlorine.—The effect of passing chlorine, together with naphthalene vapour, through a red-hot tube was also tried in such a way that the vapours should only come into contact in the hot tube. It was then found that complete decomposition took place, with large separation of carbon in dense black smoke.

I cannot conclude without heartily thanking Mr. Barrow, in the laboratory of whose works these experiments were carried out, for his kind assistance. My sincere thanks are also due to Professor Roscoe and Mr. Schorlemmer for their kindness in placing the combustion-apparatus in Owen's College laboratory at my disposal, and for their kind attention to me whilst there engaged.

ON A PARAFFIN HAVING A HIGH MELTING-POINT.

By JOHN GALLETLY.

IN manufacturing paraffin oil from Boghead coal, I happened to have at one time as the final portion of the crude oil condenser, an old boiler to which the entrance and exit pipes were attached close to the top, so that it could become nearly filled with naphtha without the passage of the gas through it being stopped. This portion of the condenser never became warm in the slightest degree, but besides filling rapidly with naphtha, a considerable quantity of a dark tarry matter accumulated in it which had a brittle crystalline feeling when pressed between the fingers. This, I supposed at first, was due to the presence of a crystalline substance, but subsequently found it was owing to the manner in which the tarry matter encrusts itself as it condenses or deposits. When this solid matter is boiled with naphtha, a thick fused cake is found to settle down, and a dark brown powder remains floating through the liquid. On filtering, a very dark coloured fluid is obtained, which solidifies on cooling, and the brown powder remains on the filter. The fused cake and this dark powder are insoluble in any ordinary liquid in which bituminous matters dissolve, not volatile without decomposition, and therefore furnishing no easy means of purification or recognition as definite substances.

On pressing the naphtha solution after cooling and solidification, the crude hydrocarbon which forms the subject of this notice, is obtained as a soft dark coloured cake. Its purification is effected by repeated crystallisations from naphtha, which are easy enough for the first three or four times, but then become very troublesome on account of the paraffin passing through the cloth along with the naphtha. Bees'-wax behaves in a similar manner when an attempt is made to crystallise it, and it would be almost as easy to press starch-paste into a firm cake. However, I used very gentle pressure in woollen cloths, allowing the mother-liquor to soak into dry bricks. This was repeated eight or ten times, using with the last naphtha a little animal charcoal. The product, after being filtered, had steam blown through it to expel the naphtha, when hard cakes were obtained of a yellowish colour. This yellow colour was no doubt due to a very small quantity of some impurity very difficult to remove.

As thus obtained this substance resembles bees'-wax very closely, but is a little more translucent and does not exhibit any conchoidal fracture when broken. It has a much harder ring than ordinary paraffins when two pieces of it are struck together. Its melting-point is very high, being 80° C. This it attains after the first few crystallisations, and remains unaltered however often this process be repeated with considerable quantities of fresh naphtha. It is evidently, then, an individual substance, not a mixture of several homologues like ordinary paraffins. It seems to be separated from the paraffins accompanying it in the crude oil by a considerable gap. The highest of these after more than a dozen crystallisations, the later of which making little alteration, had a melting-point of 65.5° C.; the quantity obtained being reduced to a fifteenth of the weight of the material commenced with, which was paraffin melting at 56° C.

The elementary composition of this paraffin is sensibly that of the other paraffins and of olefant gas. Below are the numbers I obtained alongside the analyses of some other paraffins, and the composition of olefant gas.

	Paraffin 80° C.	Olefant gas.	Anderson from Boghead 52°.	Brodie from	
				Chinese wax 58°.	Bees'- wax 62°.
Carbon ..	85.2	85.7	85.75	84.90	85.31
Hydrogen ..	14.4	14.3	15.40	14.21	14.44

By placing the composition of olefant gas alongside these analyses, I do not mean to differ with those chemists

who regard the paraffins as homologues of marsh-gas. On the contrary, I think the very existence of this new body, which must have a very complex molecule, as so much evidence in favour of this view, the marsh gas series being so much more stable than the olefines. The numbers, however, are useful as showing among other things that the elementary composition as determined by experiment cannot settle the question.

Besides the boiling-point being very high, namely, not far short of a red heat, this paraffin partially suffers a change on distillation, apparently about one-half of it being converted into liquid hydrocarbons. This renders a determination of its vapour density unusually difficult, and I have not attempted it.

I may state that the solid portion, after distillation, on being washed and crystallised from naphtha, retains its melting-point unaltered.

It seems to be a rule that the paraffins obtained from any particular source have solubilities diminishing as their melting-points get higher. The body under notice is not an exception to this rule, and the following table gives the solubility of several paraffins in well rectified commercial benzole:—

Melting-point of Paraffin.	Solubility in 100 c.c. at 18° C.
35° 0' C.	133.0 grms.
49° 6' C.	6.0 "
52° 8' C.	4.7 "
65° 5' C.	1.4 "
80° 0' C.	0.1 "

Although only one part of the paraffin melting at 80° C. dissolves in 1000 of benzole at 18° C., it mixes with it in all proportions above its melting-point.

The densities of the paraffins also show an increase with a rise in their melting-points, but I may state that it is a little difficult to obtain exactly the same numbers with two different samples having the same melting-point. One cause of this may be owing to more or less rapid cooling, but the subject requires investigation.

The following are numbers I obtained with paraffins all from Boghead coal:—

Melting-point of Paraffin.	Specific gravity.
32° 0' C.	823.6
39° 0' C.	848.0
40° 5' C.	852.0
53° 3' C.	911.0
53° 3' C.	909.0
58° 0' C.	924.3
59° 0' C.	924.8
80° 0' C.	940.0

Brodie viewing them when he published his papers as olefines, gives the formula of cerotene as $C_{27}H_{54}$ and its melting-point at 57° to 58° C., and melene as $C_{30}H_{60}$ with a melting-point of 62° C. It is probable enough from the properties of the hydrocarbon under consideration that its molecule contains nearly half as many more atoms as melene.

Picric acid forms no compound with this paraffin.

When melted over sulphuric acid, this body gives a greasy black mass resembling drawing-chalk. A mark made on paper with this substance is scarcely to be distinguished from that of a black-lead pencil. Sulphuric acid attacks all the paraffins more or less when highly heated with them, but more easily the higher their melting-points. The carbon which separates by acting on paraffin of 80° C. melting-point is in a state of very fine division, and when the dark cake so procured is boiled with naphtha the carbon passes along with the liquid through the pores of fine filter-paper.

Brodie has examined the action of chlorine on melted cerotene. He gets first a change to a waxy looking substance, then it turns gummy, and ultimately a transparent resin, becoming harder as more chlorine is absorbed; several weeks being required to complete the changes,

and the body $C_{27}H_{32}Cl_{22}$ being formed. With ordinary paraffin, Mr. James Young, jun., obtained a similar result up, at least, to the gummy stage, and afterwards Mr. W. MacIvor in Mr. Young's laboratory carried on the action till a brittle resin was obtained. On the high melting paraffin under notice chlorine acts much more rapidly, darkening it almost immediately, and giving, after a time, a thick black oily or gummy body, turning quite thin when gently warmed. I did not persevere further with the chlorine treatment after reaching the viscid liquid stage, but now subjected the material to distillation. Torrents of hydrochloric acid were evolved, and a small quantity of an oil of a strong, very peculiar odour. I can give no exact idea of this odour, and do not know to what substance it belongs, but I at once identified it as that of the oil Mr. Young obtained by distilling his viscid chlorinated paraffin. The residue of charcoal left after distillation was large.

Heated with nitric acid (sp. gr. 1.4) the 80° C. paraffin is converted in an hour or two chiefly into nitro-compounds, which are readily soluble in caustic alkalis. Ordinary paraffins undergo, as has been pointed out,* the same change with more protracted boiling. With the latter, besides butyric acid, there are acids of the succinic series produced, of greatly varying melting-points, but how many of them, from the difficulty in their separation and our imperfect knowledge of their distinguishing properties, it would not be easy to determine. The chief product is a thick clear oily nitro-compound, miscible with the warm nitric acid, and soluble in alkalis, giving when distilled large quantities of ammonia and the interesting pyridine bases. There does not appear to be a trace of aniline produced; very slight traces of aniline along with these bases giving with chloride of lime solution a bright characteristic green colour, obtained generally with the bases from shales poor in nitrogen.

A candle made of this high melting paraffin burns with a small but very clear smokeless flame, lasting a very long time. It would, however, be too expensive a material to manufacture for making candles. It occurs in the shale products as well as in those from the cannels, and could be obtained in some quantity if a tempting price were offered for it.

I hope to be able soon to complete another paper on paraffin. It is very striking how limited our knowledge is of this subject compared with our information regarding the benzole series and naphthalin. The derivation of its name has, it may be presumed, chiefly to answer for this condition of affairs.

ON THE CHANGE OF COLOUR PRODUCED IN CERTAIN CHEMICAL COMPOUNDS BY HEAT.†

By Professor EDWIN J. HOUSTON,
Of the Central High-School of Philadelphia.

(Concluded from p. 180).

Solids.—The reduction of temperature was obtained by the evaporation of ether, bisulphide of carbon, or liquid sulphurous acid. The liquid was placed in a metallic box, furnished with eight vertical sides. Strips of paper, on which the substances were painted, were pasted on the sides of the vessel. Corresponding strips of paper, similarly prepared, were kept for comparison. Cold was produced by blowing a blast of air from a small bellows upon the surface of the liquid. The results obtained were somewhat vitiated by the deposition of the moisture of the air on the sides of the metallic vessel. This difficulty was obviated to some extent by having the paper slip, kept for comparison, equally moist.

* I regret not having an opportunity of referring to a memoir which was published on this subject.

† From advance-abstracts of the *Journal of the Franklin Institute*. Communicated by Dr. W. H. Wall.

The results, which are open to this objection, were as follows:—

Sulphide of Mercury.—Changes from a bright red to a brighter red.

Bisulphide of Tin.—Changes from a brownish orange-yellow to a lighter brownish-yellow.

Subsulphate of Mercury.—Changes from a yellow to a greenish-yellow.

Iodide of Lead.—Changes from an orange to a lighter orange.

Chromate of Lead.—Changes from a yellowish-orange to a yellowish-green.

The substances occupying the remaining sides of the vessel did not present any appreciable change.

Liquids.—The experiments with liquids were, with a few exceptions, of an unsatisfactory character. The solvent in most cases was water, and the cold could not safely be pushed lower than the point of maximum density of the solutions. The solutions were prepared in test-tubes, in a manner similar to the experiments with heat. The limitation in the application of cold was, in all probability, the cause of the changes not being of a more decided character.

The following are among some of the substances experimented with:—

Sulphate of Copper.—Solution of a pure blue; deepens on the application of cold.

Ferrocyanide of Potassium.—Saturated solution of a nearly pure yellow; becomes tinted slightly with green.

Chloride of Copper.—Solution of a bluish-green; becomes a more decided bluish-green.

Sesquichloride of Iron.—Solution, orange-yellow; becomes an orange-yellow in which the yellow is more predominant than in the preceding.

Sesquinitrate of Iron.—Solution, orange-yellow, like the chloride.

Wishing to obtain a solution that could be exposed to a much lower temperature without freezing, a solution of the chloride of copper in ether was prepared. The colour was yellowish-green. When exposed to a low temperature by the evaporation of the bisulphide of carbon, the colour changed very decidedly to a pure green. It is purposed, at our earliest convenience, to pursue these investigations at lower temperatures obtained by means of solid carbonic acid and ether. Meanwhile, we would be much pleased if any investigators throughout the country, who may be using a solution of the solid carbonic acid in ether, would observe the action of intense cold on the ethereal solution of chloride of copper, or on any solution of a similar nature.

The law already stated seems now to have been clearly established, both by the number of cases that come under it, and by the fact that, so far, no exceptions have been noticed. It can hardly be urged, with fairness, that all coloured compounds should be equally influenced by the action of the less rapid heat vibrations, for the differences presented by bodies, as regards their transparency or opacity to light, or their diathermancy or adithermancy to heat, clearly indicate a very great difference in their molecular structure, which difference offers reasons amply sufficient to explain why the colours of some compounds should be more influenced by heat than others. Again, there can be little doubt that more extended observations will increase the great number of compounds already noticed. For instance, the well-known change from red to yellow presented by the red iodide of mercury, dissuaded us at first from submitting it to an experiment. On a careful trial, however, it was found to illustrate the law, changing to a decidedly darker red up to the temperature requisite to alter its crystalline form.

The theory also receives further support and confirmation from the following considerations.

It is well known that when a yellow and a red substance, which have no chemical action on each other, are mixed together, the resulting colour is orange. The explanation is undoubtedly to be found in the raising of the

less rapid red vibrations by the yellow, and the consequent lowering of the yellow by the red, the mean resulting vibration being that capable of producing orange light.

This case, though analogous to the change produced in colour by the action of the heat, is not strictly identical with it. In an orange substance, which emits red light when heated, the change is produced as follows:—

Its molecules, while vibrating in periods requisite to produce orange light, are, at the same time, forced to accept the less rapid vibrations of heat. They are unable to do this without lowering the rapidity of the light vibrations, and the emitted light is red. Here, however, the molecules themselves transmit red light to the ether surrounding the intermolecular spaces, which ether in its turn transmits it to the eye for the purposes of vision. Now, in the case of the orange light emitted after the commingling of a yellow and a red substance, as no change other than that of mixture is produced, we must still conceive of the particles of the red and of the yellow substance vibrating in periods requisite to produce red and yellow, and the interference taking place in the intermolecular spaces. Briefly the difference is as follows:—

In the substance whose colour is changed by heat, the molecules transmit the changed light directly to the surrounding ether, while in the commingled bodies, the change occurs in the ether surrounding the molecules. The two cases become strictly analogous when we mingle red and yellow light.

In accordance with this view, pure orange and green when mingled should produce yellow; yellow and blue, green; green and indigo, blue; and blue and violet, indigo.

When we come to the boundary of the spectrum on the light side, in other words when we come to the violet, an apparent objection meets us. We know that violet can be produced by the mingling of indigo or blue light with red. That is two lower vibrations, and one of them at the lowest extremity of the visible spectrum, produce by their mingling a resultant higher vibration, a fact certainly improbable, and seemingly at variance with theory. It must, however, not be forgotten that the violet of the spectrum marks not the limit of the etherial vibrations, but merely our power of appreciating them. The existence of higher vibrations is shown by the actinism of the spectrum, or the effect in producing chemical decomposition, existing some considerable distance beyond the violet. In fact, Herschel, by concentrating this invisible light beyond the violet, succeeded in rendering it visible, and gave its colour the name of lavender. This light is of a pale red, inclining to a tinge of violet.

The explanation is now simple. The violet of the spectrum is not produced by the mingling of the indigo or blue with the remoter or lower red, but with that of the higher red or lavender. Indeed, we are strongly led to the belief in the existence of a spectrum beyond the visible spectrum, whose colours, could the eye be trained to appreciate them, would be lighter tints of the lower colour. This spectrum would then begin with a paler, shriller, higher red, which we actually have in the lavender. The next, which will probably some day be rendered visible, would be a paler, shriller, higher orange; and so on through the yellow, green, and the other colours.

The analogy of the less rapid vibrations requisite to produce sound is in strict accordance with these considerations. Take, for instance, the note C of the natural gamut; it requires for its production, say 128 vibrations per second; if we increase the rapidity of the vibrations to 144, we get the next higher note, or D; at 160 vibrations, E; at 170½, F; at 192, G; at 213½, A; at 240, B; and at 256, or just twice the number of vibrations requisite to produce C, we get a higher note, which we call C', which though it differs from C in its pitch, and probably in its timbre, still bears to it in many respects a striking resemblance.

The visible range of coloured notes also constitute one octave, viz.—red, corresponding, say, to C; and then orange,

yellow, green, blue, indigo, and violet, corresponding respectively to D, E, F, G, A, and B. The octave, or the lavender, corresponding to C', can only be appreciated by the eye under favourable circumstances.

It is most probably more than a mere coincidence that the interval between the lower and the higher red, which is ½, is exactly the same as the interval between the higher and the lower C. Indeed, calculations we have made show a remarkable similarity in the intervals between the different colours of the spectrum, and the notes of the natural gamut with which we have compared them.

The same reasoning applies to the colours of the spectrum beyond the red, on the heat side, the next colour to which, could it be appreciated by the eye, would probably be a very dark reddish-violet, or a purple. In confirmation of this view, we have noticed that some reds, in turning into browns and blacks, possess a slight tinge of purple.

CORRESPONDENCE.

VALENCY OR ATOMICITY.

To the Editor of the Chemical News.

SIR,—Your correspondent "W. H. O." will find that the question of the apparently variable valency of iron has been discussed by Wurtz,* who adopts Friedel's hypothesis,

that this metal is a tetrad ($\text{Fe} = 56$). Until the vapour density of ferrous chloride be correctly determined, it cannot be said with certainty whether the molecular formula of this compound is $\text{Fe}^{\text{IV}}\text{Cl}_2$, or $(\text{Fe}_2)^{\text{IV}}\text{Cl}_4$, or $(\text{Fe}_n)^{2n}\text{Cl}_{2n}$; the vapour density of ferric chloride, however, shows that the molecular formula of this substance is $(\text{Fe}_2)^{\text{VI}}\text{Cl}_6$. By assuming that iron is tetravalent, these two chlorides become precisely analogous to the similar carbon chlorides, $(\text{C}_2)^{\text{IV}}\text{Cl}_4$ and $(\text{C}_2)^{\text{VI}}\text{Cl}_6$; written graphically—

The fact that the specific heat of iron shows that its atomic weight is 56 is no proof that ferrous chloride does not contain two atoms of iron: when carbon and hydrogen combine (by the electric spark), the resulting hydrocarbon contains two carbon atoms, being acetylene; when chlorine acts on excess of copper, the product is cuprous chloride, Cu_2Cl_2 ; and, similarly, when nitric acid acts on excess of mercury, the resulting substance is mercurous nitrate, $\text{Hg}_2(\text{NO}_3)_2$. By analogy, therefore, it may be predicted that the molecular formula of ferrous chloride is Fe_2Cl_4 , and hence that of the ferrous compounds generally is $(\text{Fe}_2)^{\text{IV}}\text{X}_4$.

Pyrites may be FeS_2 ; but there is no reason (except simplicity) for ascribing this formula rather than Fe_2S_4 ; and the difference between pyrites and marcasite may be expressed by the two formulæ:—

* "Leçons de Philosophie Chimique," p. 160. Paris, 1864.

Wanklyn has suggested that oxygen (=16), as usually met with in combination, may really be a double atom; thus, if $O = 8$, and O be divalent, water may be written $H_2(O_2)''$, or graphically—

the double atom of oxygen being as inseparable, ordinarily, as the Fe_2 in the ferric compounds or the C_2 in the ethyl series. Carbon oxide, however, may be viewed as containing oxygen not in this form, but as single atoms; graphically, this may be written—

when the four combining tendencies of the carbon are all saturated.

An argument in favour of this view may perhaps be drawn from the behaviour of carbon oxide when gently heated in presence of certain metals—*e.g.*, iron, cobalt, nickel; at temperatures not much exceeding the range of the mercurial thermometer the gas is decomposed, an oxide of the metal being produced and carbon being set free.* Under the same circumstances, carbon dioxide is perfectly inert, although it oxidises the metal at a red heat and upwards; from which it would appear as though the oxygen were in different conditions in these two gases respectively.

With respect to the abnormal oxides of nitrogen, Playfair and Wanklyn have shown† that, under certain conditions, nitrogen tetroxide has a vapour density corresponding with the molecular formula N_2O_4 ; but at higher temperatures, or under different conditions, the density is only one-half this, indicating the formula NO_2 . Apparently, therefore, a dissociation takes place; with nitric oxide, however, the larger vapour density has not yet been observed, *i.e.*, the gas as ordinarily met with is in this dissociated condition.

The following modification of Wanklyn's hypothesis of the double atom of oxygen is capable of accounting simply for all these observed facts and apparently abnormal valencies:—Oxygen is a triad, and has the atomic weight 8. Ordinarily, however, a double atom is met with, which is a diad, and has the atomic weight 16; denoting the single atom by the symbol $\omega''' = 8$, we have—

The molecule of free oxygen, therefore, like the precisely analogous one of phosphorus, contains four atoms, being $O_2 = \omega_4$. The following formulæ show how this view accounts for the abnormal nitrogen oxides and for carbon oxide; thus we have—

In the nitroxygen series (assuming nitrogen to be tri-valent)—

The vapour densities, and even the existence, of the other two members, N_2O_3 and N_2O_5 , are not as yet known with certainty.

The tendency of nitric oxide to take up a molecule of oxygen and pass into nitrogen-tetroxide may be readily explained by supposing that the dissociated group $N \equiv \omega$ passes into $N \equiv (\omega_3)$ by taking up ω_4 , the group $N(\omega_3)$ remaining unaltered, thus:—

This view of the constitution of oxygen may be applied to other elements: thus nitrogen itself as usually found in combination may be viewed as a complex of three atoms, each of which is triatomic and has the atomic weight $\frac{14}{3} = 4\frac{2}{3}$.

Hence, nitrogen may be trivalent or pentavalent; thus, denoting the ultimate atom by the symbol $\nu''' = 4\frac{2}{3}$, we have—

In a similar way, chlorine, bromine, and iodine may be considered, ordinarily, as complexes of three atoms, thus:—

* I. Lowthian Bell. *Journal of the Iron and Steel Institute* (1871) p. 158 *et seq.*
† *Journal of the Chemical Society*, vol. xv., p. 156.

Chlorine = $(X_3)' = Cl' = \begin{array}{c} \diagup X \\ | \\ X \end{array}$ usually monad.

Hydrochloric acid = $H(X_3)' = H-\begin{array}{c} \diagup X \\ | \\ X \end{array}$ where $X''' = \frac{35.5}{3}$

In iodine trichloride, ICl_3 , either the I is monovalent, and therefore the group Cl_3 monovalent, or I is polyvalent; thus, when $I = (I_3)$ (where $I''' = \frac{127}{3}$), iodine trichloride may be—

It is evident that all the artiad elements may similarly be considered as practically inseparable complexes of trivalent atoms. Thus carbon may be $(\kappa_2)'''$ where $\kappa''' = 6$, Brodie's graphon then would be $\kappa_6 = C_3 = 36$ (Wurtz).

On this view, carbonic oxide may be accounted for without assuming a variation in the valency of the oxygen complex atom, thus:—
